

Education Subsidy as Insurance for Fertility Choices*

Kanato Nakakuni[†]

Abstract

Macroeconomic challenges associated with low fertility have led many countries to implement pro-natal policies. I study the macroeconomic effects of a novel policy recently introduced in Japan—college subsidies—motivated by several facts suggesting that the cost of college education is a significant barrier to fertility. I construct an incomplete market, general equilibrium (GE) lifecycle model with college enrollment and fertility choices, in which altruistic parents make asset transfers to their children to support their college education. The model is calibrated using Japanese household panel data and replicates several measures of fertility elasticities consistent with empirical estimates. I find that the income-tested college subsidy provides a significant insurance effect on fertility choices under income uncertainty: having more children increases the likelihood that parents may not be able to afford their children’s education upon facing a negative income shock in the future, but the income-tested subsidy offers partial insurance against this risk. This insurance effect is particularly strong for educated parents who expect their children to attend college. Notably, the resulting fertility responses amplify the macroeconomic effects of the college subsidy—including reducing income inequality, improving welfare, and increasing education and income levels—through intergenerational linkages and GE feedback. The transitional dynamics highlight this amplification along the transition path.

Keywords: Fertility, incomplete market, overlapping generations, college subsidy

1 Introduction

In many advanced economies, the total fertility rates have fallen well below the replacement levels, following marked declines over the past half-century. Persistently low fertility accelerates demographic aging, posing macroeconomic and fiscal challenges such as labor force shortages and the sustainability of social security schemes. To mitigate these issues, governments have introduced various measures, including pro-natal policies that aim to boost fertility, such as child allowance and childcare subsidies.

This study examines a new policy in this context implemented recently in Japan: college education subsidies. Japan is at the forefront of demographic change, characterized by low fertility and population aging. Descriptive evidence based on household panel survey suggests that the cost of college education—primarily borne by parents in Japan rather than by students themselves or by governments—is a significant barrier to fertility.¹

What are the macroeconomic consequences of college subsidies, taking into account their effects on fertility choices? This question is relevant not only to Japan but also to other countries. Parallel to declining fertility rates, the educational attainment of the population has been increasing worldwide, implying that parents have fewer children while investing more in children’s education than before.² Empirical studies on pro-natal cash transfers indicate that reducing the (expected) financial costs of having children significantly increases fertility (e.g., [Malkova, 2018](#)) and, consistent with this evidence, a cross-country panel regression shows that the “generosity” of college subsidies is positively and significantly associated with the total fertility rate.³ Therefore, even in countries where college education is relatively inexpensive due to generous government subsidies, this study remains relevant for understanding the roles of existing subsidy schemes and their potential effects on fertility and associated macroeconomic outcomes.

My main contribution is twofold. The first is to show that the fertility choices are important to consider for evaluating the macroeconomic effects of college subsidies. I find that an income-tested college subsidy, which was recently introduced in Japan as a pro-natal measure⁴ and also prevalent across other countries, acts as partial insurance for fertility choices: having more children increases the likelihood that parents may not be able to afford their children’s education upon facing a negative income shock in the future,

¹Appendix C. discusses this point in detail, presenting several key facts: (1) the government has subsidized higher education far less than in other countries, while generously subsidizing other education stages at comparable levels to other countries; (2) a 65% gap exists in financial costs between those who have children enrolled in college and those who do not; (3) although college enrollment rates are around 55%, approximately 80% of parents aspire for their children to pursue higher education; (4) couples stop at fewer children than their ideal number, primarily because “the cost of raising and educating them is too expensive.” and (5) children’s college enrollment is associated with a higher likelihood of parents stopping at fewer children due to the financial reason.

²See, for example, [Greenwood, Guner, and Marto \(2023\)](#); [Kitao and Nakakuni \(2024\)](#).

³The “generosity” of college subsidy is measured by government expenditures on higher education per student relative to GDP per capita, and I control for country- and time-fixed effects and other covariates in the regression. See Appendix D.(iii) for details.

⁴They stated its pro-natal motive in an act enacted for the policy: “*The aim is ... to foster an environment where people can bear and raise their children with a sense of ease by alleviating the economic burden associated with higher education, thereby contributing to addressing the rapid decline in the birthrate in our country.*” (Act on Support for Higher Education Studies, enacted on May 17, 2019). See, https://www.next.go.jp/a_menu/koutou/hutankeigen/detail/__icsFiles/afieldfile/2019/05/17/1417025_02_1.pdf (available only in Japanese).

but the income-tested subsidy offers partial insurance against this risk. In addition, the resulting fertility responses amplify the macroeconomic effects of the college subsidy—such as inequality reduction, welfare improvement, and increasing income levels—through the associated general equilibrium (GE) effects and intergenerational linkages. These new findings build on the second contribution from the modeling viewpoint: the construction of a GE lifecycle model that integrates fertility and college enrollment choices.

My analysis begins with a simple analytical model of fertility choices with uninsurable income risk to highlight an insurance effect of income-tested subsidies on fertility. In this model, ex-ante identical households make fertility choices under income uncertainty, with spending on children assumed to be fixed and exogenously given, and income levels are realized after fertility choices are made. Having children can ex-post become very costly in utility terms following a bad income realization because, if they have more children, a negative shock results in significantly lower consumption (or, fewer spending on children if it were endogenous) compared to having fewer children, leading to higher marginal utilities. However, parents cannot “reduce” the number of children after facing a bad income shock as fertility choices are irreversible. Therefore, income uncertainty may make parents hesitate to have an additional child, leading to lower fertility—a relationship that is empirically supported by previous studies.⁵ I consider an income-tested subsidy that redistributes income from households with positive (good) income shocks to those with negative (bad) shocks, ensuring that the expected value of the subsidy received is zero. This design rules out effects on fertility driven by lower expected costs of children, which I refer to as an *average effect*. I show that, despite the absence of the average effect, income-tested subsidies increase fertility by smoothing marginal utilities conditional on having more children, which can be interpreted as an *insurance effect* of the subsidy.

To evaluate the quantitative importance of this insurance effect relative to other potential effects, which is informative to policy design, and to examine the macroeconomic effects associated with those fertility margins, I develop an incomplete market, GE overlapping generation (OLG) model with several key elements: (1) fertility choices about how many children to have, (2) college enrollment choices, (3) intergenerational linkages between parents and children through asset transfers and exogenous transmission of innate abilities and tastes for education, and (4) imperfect substitutability among workers with different educational background in the aggregate production function.

The model is calibrated using the Japanese Panel Survey of Consumers (JPSC) and replicates key empirical moments such as the amount of asset transfers from parents to children enrolling in college and intergenerational persistence of education status. I also estimate the AR(1) income process for different education groups using the data. Importantly, the model replicates several measures of fertility elasticities as non-targeted moments: (1) fertility elasticity with respect to government cash transfers to households with children, reported in previous empirical studies (e.g., [Milligan, 2005](#); [Malkova, 2018](#)), (2) the cross country estimate of fertility elasticity with respect to college subsidy, and (3) fertility differentials between college graduate and high school graduate parents.

In the benchmark model, college students can access government-provided student loans that mimic the actual ones in Japan, which are income- and ability-tested, while

⁵See, for example, [Modena et al. \(2014\)](#); [Guner et al. \(2024\)](#).

grants are unavailable, reflecting the situation in Japan before 2020.⁶ I then conduct several experiments using the model, including the introduction of income-tested grants implemented in 2020. These grants provide cash transfers to college students from households in the bottom 15% of the income distribution, and per-student grants amount to two-thirds of the average expenses of college students.

The main findings are summarized as follows. First, the direct effects of introducing the income-tested subsidy—defined as the effects of the subsidy while holding prices, tax rates, and household distribution constant—indicate a 2.1% increase in fertility. A decomposition analysis reveals that insurance effects play more significant roles than average effects: 62% of the direct effects on fertility are explained by the insurance effect, while 38% are due to the average effect.

Next, I also find that these fertility responses amplify the policy’s effects on inequality reduction, welfare improvement, and raising education and output levels in the long run, according to the following mechanism. First, the positive effect on fertility is more significant among college graduates since their children are more likely to attend college and are more likely to be eligible for the subsidy. Given intergenerational linkages via abilities, tastes, and assets, a higher fertility among college graduates implies that the children born due to the policy are more likely to attend college. Therefore, the policy contributes to a higher share of college graduates in the long run if we take into account these fertility responses. Second, a higher college enrollment rate leads to a lower skill premium in equilibrium. Third, the higher enrollment rate also leads to a greater accumulation of aggregate human capital and per-capita output and, thereby, and the greater tax bases and a lower equilibrium tax rates. Fourth, these effects (i.e., a higher probability of attending college, higher expected income, lower inequality, and lower taxes), induced by the fertility responses and associated GE effects, bring more significant welfare gains for newborn agents under the veil of ignorance. This amplification is highlighted by comparing the results with those under an *exogenous fertility* setup, both at the steady state and during transitional dynamics.

The marginal expansion of the policy by setting a higher income threshold further increases college graduates’ fertility, and this fertility response contributes to a higher college enrollment rate via intergenerational linkages. However, this expansion reduces the fertility of high school graduates because it significantly increases the intergenerational mobility of education and results in a “quantity-quality trade-off” of children. Also, the positive effects on output in expansion diminish since the broader coverage significantly crowds out labor supply and savings among households with children.

2 Related Literature

This paper contributes to several strands of literature. The first is the macroeconomic analysis of college education subsidies.⁷ I incorporate fertility choices into a framework

⁶This model does not allow students to access financial aid (grants or loans) provided by institutions besides the government (e.g., colleges or other private entities). In 2018, among students in four-year universities who used any financial aid, 83.8% used only government-provided aid, 8.6% used only non-government-provided aid, and 7.6% used both, according to the Student Life Survey (SLS, 2018).

⁷See, for example, Benabou (2002); Akyol and Athreya (2005); Krueger and Ludwig (2016); Lawson (2017); Abbott, Gallipoli, Meghir, and Violante (2019); Lee and Seshadri (2019); Matsuda and Mazur

that is otherwise standard in the literature (i.e., the heterogeneous-agent GE-OLG model with IVT and college enrollment choices). Based on this extended framework, this study contributes to the literature by finding the critical roles of fertility margins in understanding the macroeconomic roles of college education subsidies.

Second, this study is closely related to the literature on fertility choices in incomplete market models and, in general, on the implications of heterogeneous family structures under incomplete markets.⁸ Previous studies demonstrate that having a child can be considered making “consumption commitments,” and that income volatility thus makes households hesitate to have children.⁹ This study contributes to the literature by examining policies that can potentially insure against the risks associated with having a child and highlights the insurance effects of income-tested college subsidies on fertility choices.

Third, this study is closely related to macroeconomic studies based on the quantity-quality trade-off framework.¹⁰ I contribute to the literature by highlighting the insurance role of education policies in fertility choices and their macroeconomic implications.

Finally, this study contributes to the literature on pro-natal policies using structural models¹¹ by adding information about the effects of college subsidies, a novel pro-natal policy implemented in Japan. Compared with typical pro-natal transfers such as baby bonuses, the notable feature of the education subsidy is that it increases the average human capital by promoting skill acquisition.¹² By examining this novel policy in Japan, this study provides insights into countries considering countermeasures against macroeconomic challenges of low fertility.

3 An Illustrative Model

This section constructs a simple analytical model of fertility choices with uninsurable income risk to highlight the insurance effect of income-tested subsidies on fertility.¹³

Setup: Consider a decision problem where ex-ante identical households choose the number of children $n \geq 0$ and consumption c , facing uninsurable income risk, to maximize

(2022); Matsuda (2022); Krueger, Ludwig, and Popova (2024).

⁸For example, Cubeddu and Ríos-Rull (2003); Schoonbroodt and Tertilt (2014); Vandenbroucke (2014); Santos and Weiss (2016); Sommer (2016); Bacher, Grübener, and Nord (2024); Coskun and Dalgic (2024); Guner, Kaya, and Sánchez-Marcos (2024).

⁹This is the case, especially in the early stages of their lives, thus delaying marriage and fertility (Santos and Weiss, 2016). Delaying fertility leads to low fertility, given that the ability to reproduce declines with age (Sommer, 2016).

¹⁰For example, De La Croix and Doepke (2003); Manuelli and Seshadri (2009); Cordoba, Liu, and Ripoll (2019); Daruich and Kozłowski (2020); Zhou (2022); Kim, Tertilt, and Yum (2023).

¹¹Previous studies examine the effects of childcare subsidization (e.g., Bick, 2016), cash transfers (e.g., Kim, Tertilt, and Yum, 2023; Nakakuni, 2024), both of them (e.g., Hagiwara, 2021; Zhou, 2022), parental leave policies (e.g., Erosa, Fuster, and Restuccia, 2010; Yamaguchi, 2019; Wang, 2022; Kim and Yum, 2023), and tax reform (e.g., Jakobsen, Jørgensen, and Low, 2022).

¹²Previous studies show that pro-natal transfers would lower aggregate human capital because they make parents shift from the “quality” toward “quantity” of children (e.g., Zhou, 2022; Kim et al., 2023). Actually, Appendix M. shows that the income-tested grants would lead to greater aggregate human capital and output than pro-natal transfers conducted in an expenditure-neutral way.

¹³Appendix B. presents a special case of this model and shows that a mean-preserving spread of the income distribution leads to lower fertility.

their expected utility, $\mathbb{E}U(n, c) = b(n) + \mathbb{E}V(c)$. For simplicity, this model assumes that the number of children is a continuous variable and needs to be positive. The household first chooses the number of children n , before an income level I is realized. After making the fertility choices, an income level is realized, which is drawn from a distribution $F(I)$. The price of the consumption goods is normalized to one, and having children takes a fixed cost $\underline{a}$, net of the government subsidy $\bar{g}(I)$. Let $a(I) = \underline{a} - \bar{g}(I)$ be the (net) unit costs of having a child. The household problem is formulated as follows:

$$\begin{aligned} & \max_{n \geq 0} \{b(n) + \mathbb{E}_I V(c)\} \\ \text{s.t. } & c + n \cdot a(I) = I, \quad I \sim F(I), \\ & a(I) = \underline{a} - \bar{g}(I). \end{aligned}$$

The first-order condition: The first-order condition implies that the optimal choices (n, c) satisfy the following condition:

$$b'(n) = \mathbb{E}[a(I) \cdot V'(c)], \quad (1)$$

where a variable with the prime indicates the first-order derivative with respect to the argument. The left-hand side of (1) indicates the marginal utility of having children. The right-hand side indicates the expected marginal costs of having children, which consists of the unit costs of children ($a(I)$) and the marginal utility from consumption ($V'(c)$), where the latter is the opportunity costs of having children in terms of utility. When they make fertility choices, the marginal costs of having children are uncertain because the amount of subsidy received and consumption level are uncertain; either source of uncertainty is income uncertainty.

Assumptions: To understand the effects of the income-tested subsidy on fertility, I make the following assumptions on functional forms.

First, the utility function of children $b(n)$ takes the form of the constant relative risk aversion utility function, $n^{1-\sigma}/(1-\sigma)$, with some positive value $\sigma > 0$, and the utility function for consumption V satisfies the following properties: (1) $V' > 0$, (2) $V'' < 0$, and (3) $V''' > 0$. Second, the subsidy function $\bar{g}(I)$ takes the form $g(I; \varepsilon) = (\mathbb{E}I - I) \cdot \varepsilon$, where $\varepsilon \geq 0$ is a policy parameter that governs the degree of the redistribution. Note that such a subsidy function $g(I; \varepsilon)$ implies that (1) the subsidy is income-contingent (or income-tested) and that households with lower income realization than average receive more, while those with higher income realization than average receive a negative subsidy or incur “tax,” and (2) the expected costs of children are given as a constant, $\underline{a}$, because the expected values for the subsidy is zero for any ε (i.e., $\mathbb{E}g(I; \varepsilon) = \mathbb{E}(\mathbb{E}I - I) \cdot \varepsilon = 0$).

The first-order condition implies that the optimal fertility choice is characterized as:

$$n = \{\mathbb{E}[a(I) \cdot V'(c)]\}^{-\frac{1}{\sigma}}$$

For convenience, from now on, I express the optimal choices for consumption and number of children as functions of the parameter ε , $c(\varepsilon)$ and $n(\varepsilon)$. I define a parameter space for

ε as $\mathcal{E} \equiv \{\varepsilon \mid 1 - \varepsilon \cdot n(\varepsilon) > 0 \text{ \& } \varepsilon \geq 0\}$, which is to ensure that $\partial c / \partial I > 0$ and thus $\partial V'(c) / \partial I < 0$.

Effects of income-tested subsidy on fertility: To understand the roles of income-tested subsidy on fertility, I compare the optimal fertility choice based on an economy with some positive $\varepsilon \in \mathcal{E}$ with that with $\varepsilon = 0$, $n(\varepsilon)$ and $n(0)$. The ratio between $n(\varepsilon)$ and $n(0)$ can be written as follows:

$$\frac{n(\varepsilon)}{n(0)} = \left\{ \frac{\mathbb{E}V'(c(\varepsilon))}{\mathbb{E}V'(c(0))} - \text{cov}(g(I; \varepsilon), V'(c(\varepsilon))) \cdot B \right\}^{-\frac{1}{\sigma}} > 1, \quad (2)$$

where $B = (\underline{a} \cdot \mathbb{E}V'(c(0)))^{-1} > 0$, and the inequality (2) implies that the fertility rate with an income-tested subsidy with $\varepsilon \in \mathcal{E}$ is greater than that without the subsidy:

$$n(\varepsilon) > n(0)$$

The derivation of equation (2) can be found in Appendix D., and here I provide the intuition of why this income-tested subsidy leads to a higher fertility.

First, having one more child is costly in utility terms because it makes households give up consumption that otherwise they can. Such marginal costs of having children consist of the expected monetary costs of children and the expected marginal utility from consumption, which are the opportunity costs of having children. Recall that the expected monetary costs are identical across different subsidy schemes characterized by different $\varepsilon \in \mathcal{E}$. Therefore, it is only the expected marginal utility from consumption ($\mathbb{E}V'(c(\varepsilon))$) that makes a difference across different subsidy schemes.

If they have more children, a bad income shock is more costly in marginal utility because, holding the monetary costs of children constant, it leads to lower consumption. Given that having children is an irreversible choice, households cannot adjust the number of children after observing an income level. If a subsidy $\bar{g}(I)$ is available, such costs of having children in marginal utility from consumption become lower because they can receive some cash transfers after facing a bad income shock. It is also true that the subsidy imposes some costs for those with higher income realization. However, the benefit of this insurance is greater than those costs, given that the third-order derivative of the utility function of consumption is positive (i.e., $V''' > 0$).

To recap, the intuition behind the higher fertility due to the income-tested subsidy is that (1) having children can be, ex-post, significantly costly in terms of foregone consumption and the resulting higher marginal utility, (2) an income-tested subsidy smooths the marginal utility to some extent, which we can interpret it as partial insurance against the high (marginal) utility costs of children induced by income shocks, and (3) the benefit of insurance is more significant than the costs of paying “tax” upon a good income realization if $V''' > 0$.

Next steps: This section presents a simple analytical model and demonstrates that income-tested subsidies can positively impact fertility by providing insurance for fertility choices under income uncertainty.

The relevant questions are: (1) to what extent does an income-tested subsidy (for

education) in the real world have such an insurance role? and (2) what are the implications of the fertility responses for other macroeconomic ingredients, such as aggregate output and income distribution? This model is too simple to answer these questions in that it abstracts several critical ingredients, such as (i) more realistic income process over the lifecycle, (ii) saving decisions as a self-insurance against income risk, (iii) endogenous choices on how much money to spend in children, and (iv) production and the general equilibrium setup, which enables us to examine the macroeconomic implications. The next section thus constructs a quantitative macroeconomic model that incorporates those ingredients.

4 Quantitative Model

I incorporate fertility choices into a model otherwise standard in the macroeconomic literature of college financial aid policies: the heterogeneous-agent GE-OLG model with IVT and college enrollment choices. Section 4.1 provides an overview of the lifecycle of this economy. Section 4.2 elaborates on preliminaries of the model and then Section 4.3 formulates households' decision problems. Section 4.6 discusses the stationary equilibrium of this economy.

4.1 Overview of the lifecycle

Fig 1 represents the households' lifecycle in this model. Time is discrete, and one period corresponds to two years in this model. Let j denote the agents' age. They live with their parents until they graduate from high school at the beginning of age $j = J_E(= 18)$; until then, they make no decisions. After graduating high school, they choose whether to attend college or enter the labor market after graduating high school, represented as a node "Grad.HS" in the figure. If they do not enroll in college, they enter the labor market as a high school graduate. If they choose to attend college, it takes four years (two model periods) to complete, and they enter the labor market as a college graduate after graduation, represented as a node "Grad.CL" in the figure.¹⁴

After completing their education, they enter the labor market. At the beginning of age $j = J_F(= 30)$, they make fertility choices by choosing how many children they have, $n \in \{0, 1, 2, 3, 4\}$. The timing of the fertility choice is common for high school and college graduates. The lifecycle of a new cohort starts at this point (provided that the fertility rate is positive), represented in the bottom half of Fig 1. After their children (if they have any) graduate from high school, corresponding to the beginning of the age $j = J_{IVT}(= 48)$ for parents, they decide how much money to transfer to their children. This IVT decision affects the children's college enrollment choices at the node "Grad.HS." Households retire from the labor market at the beginning of age $j = J_R(= 66)$. After that period, they face mortality risks; every period, a certain fraction of them is hit by exogenous mortality shocks and exits from the economy. They can live for $J(= 104)$ years at the longest, and they exit the economy after age J .

¹⁴This model does not consider the possibility of dropping out from college because, as I mentioned, the dropout rate is insignificant in Japan.

Fig 1: Model's lifecycle.

Dividing the model's lifecycle into several stages, summarized in Table 1, helps us understand its structure; according to these stages, I formulate household problems in Section 4.3. Also, to provide a whole picture of the model's lifecycle, I provide lists of choices and state variables in Tables 2 and 3 in advance, including their relevant stages. Each variable is elaborated on in the following.

Stages	Corresponding age
(1) Education stage	18(−21)
(2) Early working stage (before fertility stage)	18(22) − 29
(3) Fertility stage	30
(4) Middle working stage (with children if applicable)	30 − 47
(5) Inter vivos transfers (IVTs) stage	48
(6) Late working stage (after children become independent)	48 − 65
(7) Retirement stage	66−

Table 1: The lifecycle stages and the corresponding age. *Note:* Numbers in parentheses indicate the corresponding age for those who choose to attend college.

Notation	Age/Period	Description
Throughout the entire stages		
$c > 0$	18–	Consumption
$l \in [0, 1]$	18–	Leisure
$a' \in [\underline{A}, \infty)$	18–	Asset
Education stage		
$e \in \{0, 1\}$	18	Education: college (=1) or high-school (=0)
Fertility, middle working, & IVT stages		
$n \in \{0, 1, 2, 3, 4\}$	30	The number of children (fertility)
$q > 0$	30 – 47	Expenditures on children
$a_{IVT} \geq 0$	48	Inter vivos transfers

Table 2: Summary of the choice variables over the life stages. *Note:* The borrowing limit, $\underline{A}$, varies over the lifecycle, as discussed in the following sections.

Notation	Age/Period	Description
Throughout the entire stages		
j	18–	Age
a	18–	Asset
Until retirement		
z	18(22) – 65	Labor productivity $\sim$ AR(1)
e	18(22) – 65	Education: college (=1) or high-school (=0)
h	18 – 65	Innate ability
Education stage		
ϕ	18	Psychic costs of college enrollment
I	18(–21)	Household income
Middle working stage		
n	30 – 48	The number of children
Inter vivos transfers stage		
h_k	48	Children’s innate ability endowment
ϕ_k	48	Children’s psychic costs of college education

Table 3: Summary of the state variables over the life stages. *Note:* Numbers in parentheses indicate the corresponding age for those who choose to attend college.

4.2 Preliminaries

Demographics: Every period, a mass of new cohorts enters the economy. The size of the new cohort is endogenously determined according to fertility choices of cohorts in the

fertility stage. The age distribution of this economy is thus determined by (1) households' fertility choices, which are endogenous, and (2) mortality risks after retirement, which are exogenous. Let $\zeta_{j,j+1}$ denote the probability of surviving at age $j + 1$ conditional on surviving at age j for each $j \in \{J_R, \dots, J\}$ with $\zeta_{J,J+1} = 0$.

Intergenerational Linkages and Initial Endowments: After graduating high school (at the beginning of age 18), agents are endowed with a triple (a_{IVT}, h, ϕ) : (1) assets transferred from their parents (a_{IVT}), (2) innate ability (h), which governs education returns in future earnings, and (3) psychic costs of college education (ϕ). They draw the innate ability from a distribution $g_{h_p}^h$, varying with the parents' innate ability level h_p . They also draw the psychic costs from a distribution g_{h,e_p}^ϕ , varying with the student's innate ability h and parent's education e_p .

Preferences: Throughout their lifetime, they draw utility from consumption c and leisure l according to a utility function $u(c, l)$. They discount future utility by β . At age $j = J_F$, they choose the number of children they have, denoted by $n \in \{0, 1, 2, 3, 4\}$. They draw additional utility from having children in several ways. First, they draw utility from expenditures q per child until the children graduate from high school, captured by a utility function $v(q)$. The utility $v(q)$ is discounted by a function $b(n)$, increasing and concave in the number of children n . Further, based on altruistic motives, parents draw utility by transferring assets to their children after the children graduate from high school. More specifically, parents consider children's expected lifetime utility in their education stage, with a discount rate $\lambda_a \cdot b(n)$, where λ_a represents the altruistic discount factor.

Costs of Children: Having children is costly in terms of both money and time. First, raising n children requires $n \cdot q$ units of money, where q represents the per-child expenditure. Also, they will make an additional expenditure $n \cdot a_{IVT}$ upon high school graduation of their children.¹⁵ In addition to the monetary costs, having a child requires κ units of time until the child graduates from high school and becomes independent.

Labor Earnings: Households choose hours worked to earn income. The labor earnings of a household are given by $w_e \eta_{j,z,e,h} (T - l)$; it is a product of the market wage w_e , labor efficiency or productivity $\eta_{j,z,e,h}$, and hours worked $(T - l)$. The market wage w_e depends on the education level $e \in \{0, 1\}$, where $e = 0$ and $e = 1$ represent high school and college graduates. Here, T denotes the disposable time that can be devoted to work or leisure where $T = 1 - \kappa \cdot n$ if they have n children who have not graduated high school and $T = 1$ otherwise. Labor efficiency depends on age j , idiosyncratic productivity shock component z , education level e , and innate ability h . The idiosyncratic component z follows a Markov process $\pi_z(z, z^-)$, where z^- denotes the component in the previous period.

Financial Markets: Financial markets are incomplete due to the lack of state-contingent claims. Households can self-insure against negative labor productivity shocks by savings,

¹⁵Children within a household are homogeneous, as assumed in the literature (e.g., [Abbott, Gallipoli, Meghir, and Violante, 2019](#)). Thus, education spending and IVT do not vary among children within the household.

accruing interest payments at a rate of r . Households in the working stages can borrow at rate $r^- = r + \iota$ where $\iota > 0$ (i.e., borrowers incur the overseeing costs ι) up to a borrowing limit $\underline{A}$. In contrast, retired households are not allowed to borrow, which is a common assumption in the literature. In addition, eligible students have access to student loans subsidized by the government, which entails the interest rate of $r^s = r + \iota_s$. This loan is income- and ability-tested, and eligible students can borrow up to a limit $\underline{A}_s$.

4.3 Household Problems

This section discusses and formulates household problems in each stage defined in Table 1. The first is the education stage in which they choose whether to attend college or enter the labor market after graduating high school.

(1) Education Stage: The state variables for the students are comprised of asset a_{IVT} , the innate ability h , psychic costs ϕ , and their parent's income I . They compare the expected value for entering the labor market as a high school graduate, $\mathbb{E}V^w$, with the value for enrolling in college, V_{g1} net of the psychic cost ϕ . They choose college enrollment if the latter is greater than the former; otherwise, they enter the labor market. The decision problem is formulated as follows:

$$V_{g0}(a_{IVT}, \phi, h, I) = \max_{e \in \{0,1\}} \left\{ (1-e) \cdot \underbrace{\mathbb{E}_{z_0} [V^w(a_{IVT}, j=18, z_0; e=0, h)]}_{\text{Lifetime utility for high school graduates}} + e \cdot \underbrace{[V_{g1}(a_{IVT}; h, I) - \phi]}_{\text{Value of attending college}} \right\}, \quad (3)$$

where $e \in \{0, 1\}$ indicates the education choice where $e = 1$ means college enrollment and $e = 0$ does entering the labor market as a high school graduate. V^w denotes the value function for workers and returns the value the worker obtain throughout their lives if they are straight into the labor market after high school graduation. The formulation of V^w is relegated to Appendix E.. The initial draw of z , z_0 , is uncertain and is according to the invariant distribution of z . The V_{g1} represents the value of college enrollment, formulated in Appendix E.. Proceeding to college will increase their lifetime earnings, while this return from education depends on innate ability. In addition to the psychic costs, there are other two types of costs of proceeding to college. First, they have to tuition fees p_{CL} while enrolling in college. Second, although they can supply labor and earn some income, they have to spend $\bar{t}$ fraction of their time on study, which is the opportunity costs of going to college. They can fund the consumption and tuition fees through (1) transfers from their parents a_{IVT} , (2) borrowing through student loans if eligible, (3) government-provided grants if eligible, and (4) labor earnings by themselves. Students must spend a $\bar{t}$ fraction of their time on study while in college.

(2) Early Working Stage: The household problem in this period ends up with a standard lifecycle problem in which households choose consumption-savings and leisure-labor decisions. The value function is formulated in Appendix E..

(3) Fertility Stage: When they reach the age of $j = J_F$, they choose how many children they have. The state variables in this stage consist of asset position a , productivity z , education e , and innate ability h . The problem is formulated as follows:

$$V^f(a, z, e, h) = \max_{n \in \{0,1,2,3,4\}} \left\{ V^{wf}(a, j = J_F, z; e, h, n) \right\},$$

where $V^{wf}(a, j, z; e, h, n)$ in the parenthesis represents the value function for the middle working stage with children (if they choose a positive number of children, $n > 0$) represented below.

(4) Middle Working Stage (with children if applicable): The state variables in this stage consist of asset position a , age j , productivity z , education e , innate ability h , and the number of children n . The value function V^{wf} , after fertility choices until their children become independent (i.e., for age $j \in \{J_F, \dots, J_{IVT} - 1\}$), is formulated as follows:

$$\begin{aligned} V^{wf}(a, j, z; e, h, n) = & \max_{c, l, q, a'} \{ u(c/\Lambda(n), l) + b(n) \cdot v(q) \\ & + \begin{cases} \beta \mathbb{E}_{z'} [V^{wf}(a', j+1, z'; e, h, n)] & \text{if } j \in \{J_F, \dots, J_{IVT} - 2\} \\ \beta \mathbb{E}_{z', \phi_k, h_k} [V^{IVT}(a', z'; \phi_k, h_k, e, h, n)] & \text{if } j = J_{IVT} - 1 \end{cases} \} \\ \text{s.t.} & \\ & (1 + \tau_c)(c + nq) + a' = Y_{wf}, \\ & a' \geq -\underline{A}, z' \sim \pi(z', z), h_k \sim g_h^{h_k}, \phi_k \sim g_{e, h_k}^{\phi_k}, \end{aligned}$$

where

$$\begin{aligned} Y_{wf} \equiv & (1 - \tau_w)w_e \eta_{j, z, e, h} (1 - l - \kappa \cdot n) \\ & + n \cdot B + \psi + \begin{cases} (1 + (1 - \tau_a)r)a & \text{if } a \geq 0, \\ (1 + r^-)a & \text{otherwise.} \end{cases} \end{aligned}$$

Here, ϕ_k and h_k denote the psychic costs of college education and innate ability for their children. The household consumption is deflated by the equivalence scale $\Lambda(n)$, depending on the number of children n . The expenditures on children, nq , enter the budget constraint, and utility from children, $b(n) \cdot v(q)$, enters the objective function in the periods with children. V^{IVT} represents the value function for the IVT stage at $j = J_{IVT}$, which is described in the following paragraph. Households are uncertain about their children's innate ability h_k and psychic costs ϕ_k until the beginning of age $j = J_{IVT}$.

(5) Inter Vivos Transfers Stage: At the beginning of age $j = J_{IVT}$, households decide how much to transfer to their children. This timing corresponds to when the children graduate from high school and face the college enrollment choice. Two characteristics of their children are realized at this point: their psychic costs ϕ_k and innate ability h_k . After observing the realized characteristics, households choose the optimal amount of per-child

transfer a_{IVT} , formulated as follows:

$$V^{IVT}(a, z; \phi_k, h_k, e, h, n) = \max_{a_{IVT} \geq 0} \left\{ V^w(a - \tilde{a}_{IVT}, j = J_{IVT}, z; e, h) + b(n) \cdot \lambda_a \cdot V_{g0}(a_{IVT}, \phi_k, h_k, I) \right\},$$

where $\tilde{a}_{IVT} = \frac{n \cdot a_{IVT}}{1 + (1 - \tau_a)r}$ and the parent's state vector pins down household income I . They care about the lifetime utility of each child, $V_{g0}(a_{IVT}, \phi_k, h_k, I)$, based on altruism, discounted by an altruistic discount factor λ_a .

(6) Late Working Stage: At this stage for households aged $j \in \{J_{IVT}, \dots, J_{R-1}\}$, the household problem is similar to the early working stage: they make consumption-saving and leisure-labor decisions until retirement. The value function is formulated in Appendix E..

(7) Retirement Stage: At the beginning of age J_R , households are forced to retire from the labor market. After that, they spend all their time on leisure and make consumption-saving decisions. Two points differ from previous choice problems; they receive the pension benefit p from the government and face uncertainty about the next period's survival. The value function is formulated in Appendix E..

4.4 Firm

A representative firm chooses labor and capital inputs in competitive factor markets to produce final goods. There are two types of labor inputs in this economy; the college graduates (skilled) and high school graduates (unskilled). Their total labor supply in efficiency units are represented as L_{CL} and L_{HS} , respectively. I allow them to be imperfect substitutes by considering the aggregate labor in efficiency units, L , is given as:

$$L = [\omega_{HS} \cdot (L_{HS})^\chi + \omega_{CL} \cdot (L_{CL})^\chi]^{1/\chi},$$

where $\omega_{HS} \equiv 1 - \omega_{CL}$ and $\omega_{CL} \in [0, 1]$ governs the relative productivity of the skilled workers, and χ governs the elasticity of substitution between the skilled and unskilled workers. The representative firm operates with a Cobb-Douglas production function with aggregate capital K and labor L to produce the output Y :

$$Y = ZK^\alpha L^{1-\alpha},$$

where Z represents the factor neutral productivity. Capital depreciates at the rate of δ , and the firm has to incur the capital depreciation costs.

4.5 Government

The government raises the revenue by levying three types of taxes: consumption, labor income, and capital income taxes, where each tax rate is represented as τ_c , τ_w , and τ_a . In

addition, the government collects accidental bequests and devotes them to cover expenditures. They use this revenue to fund (1) the public pension benefits, which gives p units of money to retired households each period, (2) subsidized loans for college students, (3) grants for eligible college students, where the payment per eligible student is represented by $\bar{g}(I)$ where I represents household income when the student is in the education stage (i.e., their parent's age is J_{IVT}), (4) lump-sum transfers ψ that is introduced for replicating the progressivity of labor income tax schedule in a simple way following the literature, (5) cash benefits for households with children under 17 with per-child payment of B , and (6) other expenditures S . The government budget constraint is given as follows:

$$\begin{aligned} \tau_c \cdot C + \tau_w \cdot (w_{HS}L_{HS} + w_{CL}L_{CL}) + \tau_a \cdot r \int_{\mathbf{x}} \mathbb{I}_{a(\mathbf{x}) > 0} a(\mathbf{x}) dF(\mathbf{x}) + Q \\ = p \cdot \mu_{old} + (\iota - \iota_s) \cdot K_s + G + \psi + B \cdot \mu_{j \leq 17} + S, \end{aligned} \quad (4)$$

where C , Q , μ_{old} , $\mu_{j \leq 17}$, K_s , and G represent the total consumption, total accidental bequests, population mass of retired households, that of children under age 17, the total amount of borrowing by college students, and the total grant payments. The term $\tau_a \cdot r \int_{\mathbf{x}} \mathbb{I}_{a(\mathbf{x}) > 0} a(\mathbf{x}) dF(\mathbf{x})$ represents revenue from capital income taxation, where $\mathbf{x}$, $a(\mathbf{x})$, $\mathbb{I}_{a(\mathbf{x}) > 0}$, and $F(\mathbf{x})$ represent the household state space, household's policy function for savings, an indicator function returning one if $a(\mathbf{x})$ is positive, and distribution over the state space $\mathbf{x}$.

4.6 Stationary Equilibrium

I solve the stationary equilibrium of this economy. In equilibrium, households make every choice to maximize their expected utility, the firm maximizes its profit, and the government budget is balanced. Stationarity implies that the distribution over state variables is invariant. Importantly, the age distribution is determined endogenously according to households' fertility choices. See Appendix F. for the detailed definition of equilibrium and Appendix G. for the computational algorithm for solving the equilibrium.

5 Calibration

To calibrate the model, I use the Japanese Panel Survey of Consumers (JPSC), a panel survey of Japanese women and their household members. It started in 1993 with a representative sample of 1,500 women aged 24 – 34 and contains information about, for example, their income, educational background, marital status, fertility, and expenditures to detailed categories, including those on children's education. I focus on the cohort born in 1959-69, the oldest cohort of this survey, especially to compute the completed fertility and intergenerational mobility of education. I keep only married households as in previous works (e.g., Daruich and Kozłowski, 2020) because the model focuses on choices made within married households such as fertility and educational investments.¹⁶

¹⁶Hence, an agent or household in this model refers to households with two individuals. Then, "children" in this model can also be interpreted as a household unit. That is, having n children can be interpreted as reproducing $n/2$ units of households. For example, if a household has two children, it means reproducing one household unit with two individuals.

Unless otherwise mentioned, targeted moments for the parameters internally determined, described below, are computed based on the JPSC’s 1959-69 cohort data.

As is standard, I follow a two-step calibration procedure. First, I set some parameters based on the literature or estimate them outside of the model (Step 1). Then, the remaining parameters are calibrated internally to replicate a set of targeted moments (Step 2). Hereafter, I explain the functional forms and the procedure for calibrating the relevant parameters, based on each category such as preferences and technology. I also discuss how the model performs with respect to non-targeted moments.

Preferences: Instantaneous utility for households are given as follows:

$$u(c, l) = \frac{(c^\mu l^{1-\mu})^{1-\gamma}}{1-\gamma}.$$

μ is internally determined as 0.23 so that the households spend one-third of the total disposable time on market work. Instantaneous utility from expenditures on a child is given as:

$$v(q) = \lambda_q \frac{q^{1-\gamma}}{1-\gamma},$$

where λ_q is set to 0.62 so that the annual educational expenditure per child amounts to 7% of average income at age 28. The utility must be always positive (or always negative) in models of altruism with endogenous fertility, and I set $\gamma = 0.5$ following the literature (e.g., [Darulich and Kozłowski, 2020](#)). The altruistic discount factor λ_a is set to 1.03 so that the annual average IVT for college students amounts to 27% of average income at age 28.¹⁷ Following [Kim, Tertilt, and Yum \(2023\)](#), I let the discount function of the number of children $b(n)$ be non-parametric, and assume that $b(n) = b_n$ for each $n \in \{0, 1, 2, 3, 4\}$ with $b(0) = b_0 = 0$. Those parameters are determined so that the model replicates the distribution of the completed fertility. The time for studying $\bar{t}$ is set to 0.8 so that the income share of labor earnings for college students in the model is close to 21% (SLS, 2018). I assume that $\beta = 0.98$ as in [Zhou \(2022\)](#).

Financial Markets: I set the borrowing limits $\underline{A} = 20$ million yen and $\underline{A}_s = 2.88$ million yen.¹⁸ The borrowing wedges are set $\iota = 0.055$ and $\iota_s = 0.054$ so that the model approximates the share of working households with a negative net worth (54%) and the share of students borrowing from the government-provided student loans (44%).

School Taste: I assume that the psychic costs ϕ are given as $\phi = \psi_{CL} \cdot \exp(-\nu \cdot h) \cdot \tilde{\phi}$. First, ψ_{CL} governs the scale of psychic costs and thus college enrollment rate. The second term $\exp(-\nu \cdot h)$ allows high ability students to have smaller psychic costs, as standard in the literature, and ν governs the education sorting by ability. Finally, $\tilde{\phi}$ is stochastic, and the distribution depends on their parent’s education. Following [Darulich and Kozłowski](#)

¹⁷Although some parents whose children do not enroll in college make IVT in the model, the amount is negligibly small. One reason is that the marginal gains from IVT are more significant if their children attend college, as students are financially constrained, primarily because of their limited earning ability.

¹⁸The former is based on the Family Income and Expenditure Survey by the Ministry of Internal Affairs and Communications and the latter is based on the SLS (2018).

(2020), I assume that $\tilde{\phi}$ is distributed on an interval $[0, 1]$ and follows the following CDF:

$$G_{e^p}^{\tilde{\phi}} = \begin{cases} \tilde{\phi}^\omega & \text{if } e^p = 0 \\ 1 - (1 - \tilde{\phi})^\omega & \text{if } e^p = 1 \end{cases}$$

Here, ω governs the intergenerational transmission of school tastes. ψ_{CL} is set to 20.8 so that the model approximates the college enrollment rate of 37.7%. ν is set to 1 in the benchmark, and ω is set to 1.71 so that the intergenerational transition matrix of education in the model matches the data counterpart as closely as possible. Table 4 reports the transition matrix in the model and data. (i, j) -th entry of the matrix indicates the probability that children acquire skill (education) $j \in \{HS, CL\}$ given that their parent's skill is $i \in \{HS, CL\}$ in the benchmark model, and values in parentheses represent the data counterparts. The table indicates that the education level is persistent across generations: children of high school graduates attend college with a probability less than 0.3, whereas children of college graduates do with a probability approximately 0.6.

Parents/Children	High school	College
High school	0.725 (0.798)	0.275 (0.202)
College	0.412 (0.423)	0.588 (0.577)

Table 4: Intergenerational transition matrix of education. *Note:* (i, j) -th entry of the matrix indicates the probability that children acquire skill (education) $j \in \{HS, CL\}$ given that their parent's skill is $i \in \{HS, CL\}$ in the benchmark model, and values in parentheses represent the data counterparts.

Intergenerational Transmission of Ability: The intergenerational transmission of ability is according to the following formula:

$$\begin{aligned} \log(h) &= \rho_h \cdot \log(h_p) + \varepsilon_h, \\ \varepsilon_h &\sim N(0, \sigma_h). \end{aligned}$$

I set ρ_h to 0.30 to approximate the intergenerational income elasticity (0.3) and also set σ_h to 0.65 so that the variance of log income at age 28 in this model is close to 0.27.

Income Process and Education Return: The efficiency labor of an agent aged j , education e , innate ability h , and productivity z , $\eta_{j,z,e,h}$, is given as follows:

$$\begin{aligned} \log \eta_{j,z,e,h} &= \log[f^e(h)] + \gamma_{j,e} + z, \\ f^e(h) &= h + e \cdot (\alpha_{CL} h^{\beta_{CL}}), \\ z' &= \rho_e^z z + \zeta, \quad \zeta \sim N(0, \sigma_e^z). \end{aligned}$$

To set $\gamma_{j,e}$, I estimate the second-order polynomial of hourly wages on age using JPSC. As reported in Table 10 in Appendix H. (iii), the income gradient on age is larger for college graduates than the rest of the workers, but the degree is modest compared with the US case (e.g., Abbott, Gallipoli, Meghir, and Violante, 2019).

Following Daruich and Kozlowski (2020), I construct a series of two-year total household income (i.e., the sum of husband's and wife's labor earnings) for each couple and estimate the process for stochastic components z for each education group. The estimated

persistence parameters (ρ_e^z) for high school and college graduates are 0.98 and 0.97, and parameters governing income volatility (σ_e^z) for high school and college graduates are 0.02 and 0.03, which are similar to the process estimated in Daruich and Kozlowski (2020) using the US data in their levels.¹⁹ The function $f^e(h)$ indicates that the education return depends on innate ability h : people with higher innate abilities can obtain greater returns through college education. Following Daruich and Kozlowski (2020), α_{CL} and β_{CL} are determined so that the model replicates the ratio of log wage between college graduates and the rest of the population at age $j = 28$ and the log wage variance for college graduates at age $j = 28$.

Production: I set the capital share $\alpha = 0.33$ and $\delta = 0.07$ following Kitao (2015). χ is set to 0.39 following Matsuda and Mazur (2022). ω_{CL} is internally determined to 0.52 so that the average wage ratio between college graduates and the rest in the model amounts to 1.36. Z is determined so that the wage rate for high school graduates is normalized to one in the benchmark.

Government: Tax rates are set to $\tau_c = 0.1$, $\tau_w = 0.35$, and $\tau_a = 0.35$ in the benchmark. The lump-sum transfer is set to $\psi = 0.01$ to match the ratio between the variance of log net income and that of log gross income (0.6). The pension benefit p is set so that the government provides ¥160,000 per household per month. The cash transfer B , which we refer to “child benefit” or “typical pro-natal transfers” hereafter, is given as ¥10,000 per child per month, approximating the actual payment. The other expenditure S is set so that the government budget constraint is balanced in the benchmark and fixed throughout the counterfactual experiments.

Miscellaneous: The survival probability $\zeta_{j,j+1}$ is set based on the Vital Statistics (2019).²⁰ Annual college tuition fees p_{CL} are set to 1.05 million yen. κ is set to 0.044 so that they spend 13.3% of their working hours on childcare.²¹ Tables 11 and 12 in Appendix H. (iii) summarize the parameters externally determined outside the model and those internally determined inside the model. Table 5 provides the list of targeted and non-targeted moments, which are briefly discussed below.

Non-targeted Moments: The benchmark model also replicates several non-targeted moments related to fertility behavior: (1) fertility differentials between college and high school graduates, (2) fertility elasticity with respect to pro-natal cash transfers—the *benefit elasticity of fertility*—, and (3) cross-country estimate of the fertility elasticity with respect to college subsidy. I report the model-implied moments and data counterparts in these regard in Table 5, and detailed discussion is provided in Appendix H. (iv).

¹⁹The details of the estimation procedure can be found in Appendix H..

²⁰See, <https://www.mhlw.go.jp/english/database/db-hw/outline/index.html>.

6 Roles of an Income-tested College Subsidy

I introduce an income-tested college subsidy—which approximates the one actually introduced in Japan in 2020—into the calibrated model. More specifically, I allow for an income-tested subsidy for students in low-income households, whose income is below $\bar{I}$, and students in these households receive an amount g each period while they are in college. The grant function $\bar{g}(I)$ is formulated as follows:

$$\bar{g}(I) = \begin{cases} g & \text{if } I < \bar{I} \\ 0 & \text{otherwise} \end{cases} \quad (5)$$

The income threshold $\bar{I}$ in the actual policy approximately corresponds to the 15th percentile of the household income distribution, and the payment amounts to approximately two-thirds of the average college student’s expenses, including both tuition fees and living expenses.²² I set $\bar{I}$ and g based on this information, considering the income distribution and students’ expenditures in the benchmark model (initial steady state). I then analyze the effect of the subsidy on fertility (Section 6.1), its long-run macroeconomic implications (Section 6.2), and the transitional dynamics (Section 6.3).

6.1 Effects on Fertility

The main goal here is to quantify the insurance effects of the income-tested subsidy discussed in Section 3. Therefore, I first simulate the introduction of the subsidy in a partial equilibrium setup, in which prices, tax rates, and distributions are fixed as in the benchmark, and see the (direct) effect on fertility.²³

I decompose the direct effects on fertility into two effects: insurance effects and *average effects*. The insurance effects are those I discussed in Section 3. Although the illustrative model considers an income-tested subsidy with an expected value of zero, if the expected value is not zero, as in the actual policy I consider here, an additional effect arises: the average effect. The average effect captures the reduction in the expected monetary costs of having children and the resulting positive income effect on fertility.

In Appendix D. (ii), I demonstrate that the direct effects can be decomposed into insurance and average effects as follows. First, I construct a grant function that provides the present discounted value of the expected college subsidy to each household at the fertility stage, based on the joint probability that its (potential) children enroll in college and that the household is eligible for the subsidy (i.e., its income will be below the income threshold). I then compute the effects of this subsidy on fertility, referred to as the average effect, which captures the impact on fertility resulting from the reduction in the expected cost of children. My decomposition formula indicates that, under certain assumptions, the insurance effect can be computed as the difference between the overall direct effect and the average effect. Tables 15 and 14 summarize the decomposition results.

²²Although the income threshold $\bar{I}$ and payment g in the actual system vary with certain characteristics of households and students, such as family structure and whether the student commutes to college from home, I abstract away from those details for simplicity.

²³The effects on fertility in the long run, which also capture the indirect effects such as GE effect, taxation effect, and distribution effects, are reported in Appendix J.. It turns out that the direct effects explain two-thirds of the overall effects.

The main results of the decomposition are three-fold. First, the insurance effects account for 62% of the direct effects on TFR (i.e., 1.3 p.p. over a 2.1 % increase), while the average effects account for 38% (i.e., 0.8 p.p. over a 2.1% increase). This means that the insurance effect is quantitatively more important in accounting for the effect of the income-tested college subsidy on fertility. Second, the effects on fertility are more significant for college graduates (a 4.5% increase) than high school graduates (a 0.9% increase). This is because college graduates have a higher probability of being eligible, as their children are more likely to attend college, resulting in both stronger average and insurance effects for them compared to high school graduates. Third, the relative importance of insurance effects to average effects is more significant for high school graduates: the insurance effect accounts for about half of the fertility increase for college graduates, whereas it does about 90% of that for high school graduates. This is because (1) on average, college graduates are more able to self-insure against income risk due to higher earnings, and (2) since children of high school graduates are less likely to attend college, the effect of reducing the expected cost (i.e., the average effect) is generally negligible.

	<i>Average</i>	<i>Insurance</i>	Total
Total fertility rate (Δ %)	+0.8	+1.3	+2.1
High school graduates (Δ %)	+0.1	+0.8	+0.9
College graduates (Δ %)	+2.4	+2.1	+4.5

Table 6: Direct effects on fertility and decomposition results.

Although the setup of the quantitative model differs from that of a simple model presented in Section 3, the interpretation of the insurance effect still applies. First, having one more child can be, ex-post, extremely costly in utility terms in two ways after the bad income realization. First, holding the amount of IVT constant, a bad income shock can lead to an extremely low consumption level for parents if they have more children. On the contrary, holding the household consumption level constant, a bad income shock may make it infeasible for them to spend enough IVT to let their children attend college if they have more children. Both situations are costly for parents, leading to a significantly high expected marginal cost of children. If the income-tested college subsidy is available, the expected marginal costs of children in utility terms become lower because they can receive some cash after facing a bad income shock and devote it to support their children’s education.²⁴

6.2 Long-run Macroeconomic Implications

Next, I examine its long-run macroeconomic implications by solving the stationary equilibrium with the new grant function. The main result here is that the effects of introducing

²⁴Appendix N. examines other policies, including those insuring against income risks, such as (fertility-dependent) wage insurance, in an expenditure-neutral manner. I show that although the fertility-dependent wage insurance has a positive effect on fertility, the effect is smaller than the insurance effects of income-tested college subsidy. This is because the income-tested college subsidy provides partial insurance not only against income risk but also against another source of uncertainty: uncertainty regarding children’s characteristics (i.e., psychic costs and innate abilities) and the associated uncertainty regarding the willingness to pay for children’s education.

the subsidy—such as a higher college enrollment rate, lower skill premium and income inequality, and increases in output and welfare—are quantitatively more significant if we take into account endogenous fertility.

To this end, I also solve the *exogenous fertility* version of the model, where the household decision rule (policy function) on fertility, $\bar{n}(a, z, e, h)$, are fixed as in the benchmark. Note that this exogenous fertility setup is common in the macroeconomic literature on college subsidies (Krueger and Ludwig, 2016; Matsuda and Mazur, 2022, e.g.), and comparing the results under exogenous fertility with those under endogenous fertility unravels the role of fertility choices in evaluating the macroeconomic implications of a college subsidy. Table 7 reports the main results both under endogenous and exogenous fertility.

	Fertility setup	
	Endogenous	Exogenous
College enrollment (Δ p.p.)	+3.9	+2.9
Skill premium (Δ %)	−5.9	−4.6
Standard deviation of log wage (Δ %)	−1.3	−1.1
Output per capita (Δ %)	+0.7	+0.5
Labor income tax (Δ p.p.)	+0.02	+0.13
Welfare (%)	+5.1	+3.5
Marginal Value of Public Funds (Willingness to pay / Net costs of policy)	302.94	17.06

Table 7: Long-run macroeconomic implications (endogenous vs. exogenous fertility). *Note:* For “Standard deviation of log wage,” wages for an agent with (j, z, e, h) is captured as $w_e \cdot \eta_{j,z,e,h}$. Welfare gains are represented in terms of consumption equivalence for newborn agents under the veil of ignorance.

First, the policy introduction results in a 2.9 p.p. increase in the college enrollment rate under exogenous fertility, which is lower than a 3.9 p.p. increase under endogenous fertility. Under both exogenous and endogenous fertility, the grants allow some children who otherwise cannot enroll in college to enroll. Also, an increase in the college enrollment rate is amplified in the long run through a distributional effect: the composition of high-skilled individuals in younger generations increases, and when they reach parenthood, their children are more likely to enroll in college due to intergenerational linkages via assets, abilities, and tastes.²⁵

Under endogenous fertility, the college enrollment rate can further increase through an additional channel. As discussed in Section 6.1, college graduates tend to have higher fertility rates than high school graduates. Their children are more likely to attend college due to the intergenerational transmission of abilities and tastes. When these children become parents themselves, their own children, if they have any, are also likely to inherit similar traits, favoring college enrollment. In other words, fertility responses amplify the distributional effect on college enrollment. Through this fertility channel, the long-run share of college graduates increases further, explaining why the long-run college enrollment rate is higher under endogenous fertility.

²⁵A detailed decomposition exercise can be found in Section J..

A higher college enrollment rate implies a greater supply of college graduates in the labor market, leading to a reduction in the skill premium. The decline in the skill premium under endogenous fertility (-5.9%) is more significant than under exogenous fertility (-4.6%) due to higher college enrollment rates under endogenous fertility. When considering another proxy for income inequality, such as the standard deviation of log wages, the reduction in income inequality is also more significant under endogenous fertility (-1.3%) than under exogenous fertility (-1.1%), partly due to the lower skill premium.

The output per capita increases more under endogenous fertility ($+0.7\%$) than under exogenous fertility ($+0.5\%$), due to greater supply of skilled (college graduate) workers. The greater output implies the greater tax bases, leading to a lower tax rate in equilibrium under endogenous fertility (35.02%) than under exogenous fertility (35.13%). The welfare gain—measured as consumption equivalence for new born agents under the veil of ignorance—is greater under endogenous fertility ($+5.1\%$) than exogenous fertility ($+3.5\%$) because of those channels (i.e., a lower tax, lower inequality, and a higher expected lifetime income).²⁶

I also compute the average Marginal Value of Public Funds (MVPF), defined as the average willingness to pay for a policy divided by the aggregate (net) costs of the policy. The MVPF under endogenous fertility (302.94) is significantly greater than under exogenous fertility (17.06) because the policy is almost self-financing under endogenous fertility.²⁷

In Appendix K., I examine the expansion of the policy by increasing the income-threshold $\bar{I}$. The main results are two-fold. First, the expansion of the policy further increases college graduates' fertility, primarily due to the insurance effect, and this fertility response contributes to a higher college enrollment rate via intergenerational linkages. Second, the positive effects on output during expansion diminish and eventually turn negative as the threshold $\bar{I}$ becomes sufficiently high, since broader coverage significantly crowds out labor supply and savings among households with children.

6.3 Transitional Dynamics

Lastly, I investigate the transitional dynamics of the economy upon the introduction of the income-tested grants. The introduction occurs unexpectedly for households in the initial equilibrium (benchmark economy). Households have perfect foresight about future prices and tax rates and make subsequent choices to maximize utility. For computational reasons, I assume that the government collects the lump-sum taxes to balance the budget during the transition and that the labor income tax rate immediately reaches its final steady-state value, $\tau_l = 0.3502$.²⁸

The takeaway here is that it takes a long time for the macroeconomic effects to accrue, and that part of the reason is fertility responses are taken into account. For example,

²⁶In Appendix , I formulate this welfare measure and discuss theoretical and conceptual difficulties on welfare analysis with models with endogenous fertility.

²⁷Hendren and Sprung-Keyser (2020) examine the MVPFs for 133 historical policy changes over the past half-century in the U.S. and find that the MVPFs for college education subsidies were infinite in many cases, as they were self-financing. Krueger et al. (2024) also show that education policies, such as making college free and improving funding for public schooling, are more than self-financing using a GE-OLG model.

²⁸Some previous studies also adopt this strategy for computational reasons (e.g., Daruich, 2022).

the left-panel of Fig 2 represents the transition path of college enrollment rates. College enrollment rates (within cohorts) increase upon the introduction but do not immediately reach the new equilibrium value and gradually converge to it. This is because a part of the long-run increase in college enrollment rate is explained by the distribution (composition) effects: students who benefit from the policy become parents in the future, whose children will be more likely to attend college due to intergenerational persistence of assets, abilities, and tastes. Also, the fertility responses strengthen the distribution effects: college graduates increase fertility, and those “marginal” children born are more likely to be college graduates, whose children will be more likely to attend college. The roles of fertility margin can be observed in the difference between the transition path under endogenous fertility (a blue solid line) and that under exogenous fertility (a red dashed line). Both paths are nearly identical for the first 18 years after the policy introduction but begin to diverge thereafter. This divergence corresponds to the period when the first generation born after the policy starts making college enrollment choices.

Fig 2: Transitional dynamics of college enrollment rates and skill premium. *Note:* “End. fertility” and “Exo. fertility” represent transition paths under endogenous fertility and exogenous fertility.

The right-panel of Fig 2 shows the transitional path of the skill premium. It decreases over time as college enrollment rates increase. Under exogenous fertility, the skill premium reaches its final value 30 periods (60 years) after the policy introduction, whereas under endogenous fertility, it takes more than 40 periods (80 years). This is because college enrollment rates take longer to reach their final steady-state level under endogenous fertility.²⁹

7 Concluding Remarks

This paper examines the macroeconomic consequences of college subsidies by constructing a GE-OLG model that incorporates college enrollment, fertility, and inter-vivos transfer choices. My central contribution is to highlight the critical role of fertility margins in evaluating the macroeconomic performance of college education policy: (1) an income-tested

²⁹Transitional paths for other variables, such as taxes, output, and welfare, are presented in Appendix O..

college subsidy acts as partial insurance for fertility choices, and (2) the resulting fertility responses amplify the macroeconomic effects of the college subsidy—on inequality reduction, welfare improvement, and income growth—through associated general equilibrium (GE) effects and intergenerational linkages. These new findings build on another contribution: the construction of a GE model that integrates fertility and college enrollment choices.

While the current model introduces a new ingredient—fertility choices—to examine college subsidies, it, like previous studies on college financial aid policies, abstracts away from children’s skill formation through parental investments before college education.³⁰ These factors are particularly critical when considering broader policies that contribute to children’s skill formation, including family policies and early childhood education policies.³¹ In addition, this paper abstracts from competition for college admissions and externalities of parental investments, which are also important to consider when evaluating broader education policies, such as education taxes and changing enrollment capacities.³² Incorporating these factors into the current model and exploring broader education policies are left for future research.

³⁰An exception is the recent work by [Krueger, Ludwig, and Popova \(2024\)](#), which endogenizes pre-college human capital accumulation.

A. Illustrative Examples for Fertility Differentials

A. (i) The Price of Time Theory

Following [Jones, Schoonbroodt, and Tertilt \(2010\)](#), I consider the following problem:

$$\begin{aligned} \max_{c,n} & \left\{ \frac{c^{1-\sigma}}{1-\sigma} + \theta \frac{n^{1-\sigma}}{1-\sigma} \right\} \\ \text{s.t.} & \\ & c = w \cdot (1 - n \cdot \chi) \end{aligned}$$

Here, c , n , w , and χ denote consumption, fertility, an exogenous wage, and time costs of children. The optimal fertility decision n^* is given as:

$$n^* = \frac{1}{w^{\frac{1-\sigma}{\sigma}} \cdot (\chi/\theta)^{\frac{1}{\sigma}} + \chi},$$

meaning that the negative income-fertility relationship holds if $\sigma > 1$ (i.e., the substitutability between consumption and children are high enough). Because having children is time-consuming, its (opportunity) cost is higher for high-income households. At the same time, high-income households, by definition, have higher incomes and afford to have more children. If the substitutability between consumption and children is sufficiently high, the substitution effect dominates the income effect, implying the negative income-fertility relationship.

A. (ii) The Quantity-Quality Trade-off

Following [De La Croix and Doepke \(2003\)](#), I consider the following problem:

$$\begin{aligned} \max_{c,n,e} & \{\ln(c) + \theta \ln(nq)\} \\ \text{s.t.} & \\ & c + b \cdot n \cdot e = w \cdot (1 - n \cdot \chi), \\ & q = (\eta + e)^\gamma, \\ & c, n > 0, e \geq 0. \end{aligned}$$

Here, the choice variables c , n , and e represent the consumption, fertility, and per-child education investment. The investment e is transformed into the “quality” of children, q , according to a innate ability production function $q = (\eta + e)^\gamma$. The parameter $\gamma \in (0, 1)$ governs the marginal gains of investment, and $\eta > 0$ implies that the quality of children takes a positive value even if parents make no investments. Parameters χ and b represent the time cost of having a child and a unit (monetary) cost of investment.

The optimal solutions for the fertility and education investment are given as

$$e^* = \frac{\gamma w \chi / b - \eta}{1 - \gamma}, \quad (6)$$

$$n^* = \frac{1}{1 + \theta} \cdot \frac{1 - \gamma}{\chi - \eta b / w}. \quad (7)$$

There are two critical observations in the optimal choices (6) and (7): (1) the optimal number of children is decreasing in wage level w , and (2) the optimal number of children is decreasing in the investment efficiency γ whereas the optimal investment is increasing in γ . These two observations capture the main theoretical explanations for the negative relationship between income and fertility: (1) having children is more costly for higher-income households, provided that having children is time-intensive, and (2) higher-income households have higher demands for child quality or an advantage in parental investments.³³

My full quantitative model captures these two channels, contributing to replicating the fertility differentials between college and high school graduates observed in the data. First, the opportunity costs of having children are more significant for college graduates, making child-bearing more costly for them. This is because having a child requires parents to incur a fixed amount of time, and college graduates' wage rates are higher than those of high school graduates. Second, college graduate parents are more willing to pay for the IVT, making a child more costly. This is because the children's innate ability and psychic costs of education, (h_k, ϕ_k) , govern education returns and the willingness to attend college, which in turn governs the marginal gains from IVT for parents. In particular, the psychic costs of children correlate with those of parents, so college graduate parents derive higher utility from the IVTs than high school graduate parents.

B. Fertility Choices with Income Risk

This section illustrates a simple model of fertility choices under income uncertainty and shows that the higher income uncertainty leads to lower fertility. The following setup can be considered a special case of Section 3, in which no subsidy is provided and the income distribution is uniform.

Setup: I consider a household problem where a household chooses the number of children, n , and consumption, c , to maximize its expected utility while facing income uncertainty. Households first choose the number of children, n , before the realization of the income level; the income level can take on either $y - \varepsilon$ or $y + \varepsilon$, with $\varepsilon \in (0, y)$ for some $y > 0$, with equal probabilities. Let q be the unit cost of having children,³⁴ and for simplicity, the number of children chosen must be positive. After the income level is realized, they choose the consumption level, c . The household problem is formulated as

³³For more details, see Jones et al. (2010).

³⁴ q takes a positive value and is assumed to be lower than the worst income level, $y - \varepsilon$, to ensure positive consumption and fertility.

follows:

$$\begin{aligned} & \max_{n>0} \mathbb{E}_y \{U(c) + v(n)\} \\ \text{s.t.} \\ & c + q \cdot n = \begin{cases} y + \varepsilon & \text{w.p. } 1/2 \\ y - \varepsilon & \text{w.p. } 1/2 \end{cases} \end{aligned}$$

Now, based on standard assumptions on utility functions, namely that (1) $v''(n) < 0$ and (2) $U'''(c) > 0$, it holds that

$$\frac{dn}{d\varepsilon} < 0, \quad (8)$$

meaning that the higher income uncertainty leads to lower fertility.

Derivation: I first take the first-order condition with respect to n as follows:

$$\begin{aligned} q^{-1} \cdot v'(n) &= \mathbb{E}U'(c) \\ &= \frac{1}{2}[U'(y + \varepsilon - n \cdot q) + U'(y - \varepsilon - n \cdot q)] \end{aligned} \quad (9)$$

To capture the relationship between n and ε , I then express n as a function of ε and take the first-order derivatives of the both sides of equation (9) with respect to ε as follows:

$$\begin{aligned} 2q^{-1}v''(n(\varepsilon))\frac{dn}{d\varepsilon} &= U''(y + \varepsilon - q \cdot n(\varepsilon)) - U''(y - \varepsilon - q \cdot n(\varepsilon)) \\ &\quad - q \cdot \frac{dn}{d\varepsilon}[U''(y + \varepsilon - q \cdot n(\varepsilon)) + U''(y - \varepsilon - q \cdot n(\varepsilon))] \\ \Leftrightarrow 2q^{-1}v''(n(\varepsilon))\frac{dn}{d\varepsilon} + q \cdot \frac{dn}{d\varepsilon}[U''(y + \varepsilon - q \cdot n(\varepsilon)) + U''(y - \varepsilon - q \cdot n(\varepsilon))] \\ &= U''(y + \varepsilon - q \cdot n(\varepsilon)) - U''(y - \varepsilon - q \cdot n(\varepsilon)). \end{aligned}$$

Finally, we have the stated result (8) as follows:

$$\frac{dn}{d\varepsilon} = \frac{\overbrace{U''(y + \varepsilon - q \cdot n(\varepsilon)) - U''(y - \varepsilon - q \cdot n(\varepsilon))}^{>0 \text{ } (\because U'''>0)}}{\underbrace{2q^{-1}v''(n(\varepsilon)) + q \cdot [U''(y + \varepsilon - q \cdot n(\varepsilon)) + U''(y - \varepsilon - q \cdot n(\varepsilon))]}_{<0 \text{ } (\because v''<0 \text{ \& } U''<0)}} < 0$$

C. Education Costs and Fertility Choices in Japan

Japan is a leading country in demographic aging,³⁵ leading to the shrinking labor force, output, and tax base, while the public expenditures on social security benefits are in-

³⁵Japan's current fertility rate has been around 1.3, far below the population replacement level. In addition, the old-age dependency ratio is more than 50% and is projected to reach 80% in 2050, which is by far the highest among the OECD countries (See, <https://data.oecd.org/>).

creasing. As a countermeasure against this demographic issue, the government introduced grants for college students in 2020. Two key underlying premises are: (1) it will increase the “quality” of the labor force in the long run, and (2) it will increase the fertility rate, which increase the “quantity” of the labor force in the long run. This pro-natal motive is explicitly described in an act for introducing the grants.³⁶

The aim is ... to foster an environment where people can bear and raise their children with a sense of ease by alleviating the economic burden associated with higher education, thereby contributing to addressing the rapid decline in the birthrate in our country.

(Act on Support for Higher Education Studies, enacted on May 17, 2019)

Although that expectation for education policies as a pro-natal policy is unconventional, there are facts suggesting that the financial costs for parents to support their children’s college enrollment are a significant barrier to fertility in Japan. I first list the five facts below and then elaborate on each one by one:

1. Japan is one of the least in subsidizing tertiary education.
2. A 65% gap exists in financial costs between those who have children enrolled in college and those who do not.
3. About 80% of parents desire a college education for their children.
4. Couples stop at fewer children than their ideal number primarily due to financial costs.
5. Children’s college enrollment is associated with a higher likelihood of parents stopping at fewer children due to the financial reason.

Fact 1. *Japan is one of the least in subsidizing tertiary education.*

Japan is one of the least in subsidizing tertiary education, which roughly corresponds to four-year college education in Japan, given that the enrollment rates for tertiary education other than the four-year college are significantly lower than four-year college enrollment rate.³⁷

To see this, I use the cross-country data provided by the OECD³⁸ and define the *subsidization rate* for a specific education category e as follows:

$$s_e = \frac{y_e^{pub}}{y_e^{pri} + y_e^{pub}},$$

³⁶See, https://www.mext.go.jp/a_menu/koutou/hutankeigen/detail/__icsFiles/afieldfile/2019/05/17/1417025_02_1.pdf (available only in Japanese).

³⁷According to the Basic School Survey by the MEXT, the enrollment rate for some college was 4% in 2022 and is declining over the past thirty years.

³⁸I use 2018’s data given that it is the latest year in which data on a significant number of countries is available.

where y_e^{pri} and y_e^{pub} represent the private and public spending on education e , both represented as a share of the GDP. Public spending includes expenditures on educational institutions and educational-related subsidies for households or students. Private spending refers to expenditures financed by households and other private entities. Private spending includes expenditures on school but excludes those outside educational institutions (e.g., textbooks purchased by households, private tutoring, and student living costs).³⁹ In other words, the subsidization rate indicates what fraction of (potential) school-related costs are funded by the government.

As Table 3 shows, Japan subsidizes more than 90% of the costs for primary-to-secondary education, which is higher than the OECD average. On the contrary, the subsidization rate for tertiary education was only 32%, which is the second lowest among OECD countries and less than half of the OECD average of 70%. This fact shows plenty of room for increasing subsidies for college students, which also has driven recent policy discussions on introducing and expanding education subsidies for college students.

Fig 3: Subsidization rate for each education category (OECD, 2018).

Fig 4 plots the ratio of per-student government expenditures on tertiary education to per-capita GDP. On average, the government expenditures for each student enrolling in tertiary education amount to 33% of per-capita GDP, but the Japanese government only does to 21%.

³⁹For more details, see the OECD data (<https://data.oecd.org/>).

Fig 4: Per-student government spending on tertiary education to per-capita GDP (OECD, 2016-17).

Fact 2. *A 65% gap exists in financial costs between those who have children enrolled in college and those who do not.*

Fact 1 indicates that the financial cost of having children is a critical constraint on fertility choices in Japan. However, it is silent on how and in which cases having children is so expensive; Fact 2 addresses them from the viewpoint of education costs. To do this, I use two data sets: (1) the Survey of Children’s Learning Expenses (SCLE, 2021) and (2) the Student Life Survey (SLS, 2018), both cross-sectional household surveys and conducted by the Ministry of Education, Culture, Sports, Science and Technology (MEXT).⁴⁰ The SCLE covers more than 53,000 students from preschool to high school and reports the per-student average education expenditure for each expenditure category and education stage (i.e., preschool, elementary, junior high, and high school). The expenditure category includes not only school-related ones (e.g., tuition fees and textbooks) but also extracurricular activities (e.g., cram school, music, arts, and sports). In addition to that, I use the SLS for parents’ expenditures when their children enroll in college.⁴¹

⁴⁰See, https://www.mext.go.jp/b_menu/toukei/chousa03/gakushuuhi/1268091.htm for the SCLE and https://www.jasso.go.jp/statistics/gakusei_chosa/__icsFiles/afieldfile/2021/03/09/data18_all.pdf (in Japanese) for the SLS.

⁴¹In 2018, the SLS correct answers from 43,394 students attending tertiary education, including college, some college, and graduate school.

Fig 5: Average education expenditures.

Fig 6: Cumulative education-expenditures.

Fig 5 shows the average per-child expenditure for each education category until completion. “NU,” “EL,” “JH,” “HS,” and “CL” each stand for nursery school or preschool, elementary school, junior high school, high school, and college, only consisting of a four-year college. All expenditures are conditional on enrollment in the education stage. Fig 6 represents the cumulative education expenditures, showing that the expenditure jumps up when children attend college. Given that the high school graduation rate is approximately 100% in Japan, the figure tells us that raising one child on average takes the education costs of 7.31 million yen, which amounts to 4.5% of the individuals’ average lifetime labor earnings.⁴² If their children attend college, they have to spend another 4.8 million yen, meaning there is about a 65% increase in education costs if parents send their children to college. This expensiveness of college education can, at least partly, be attributed to the fact that Japan is one of the least in subsidizing tertiary education while subsidizing a sizable portion of schooling costs up to secondary education. These observations establish Fact 2: A significant financial cost gap exists between those who have children enrolled in college and those who do not.

Fact 3. *About 80% of parents desire a college education for their children.*

We return to the NFS (2015), which asked respondents about the desired education level for their children. Fig 7 summarizes the results by wife’s age. Here, “SC” stands for some college. The figure shows that approximately 75% of the parents desire a college education for their children, which is significantly higher than the college enrollment rate, which was 56.6% in 2022. This observation suggests that, although college enrollment in Japan has been far below 100%, education costs for a college education can be relevant not only for a specific part of the population because many parents would like to send their children to college.

⁴²I construct a proxy of the average individual’s lifetime earnings based on the 2022 Basic Survey on Wage Structure (BSWS) by the Ministry of Health, Labour, and Welfare (MHLW). First, I compute the average monthly earnings of ordinary workers for each age unconditional on any other characteristics such as sex and education. Then, I sum up the average earnings for each age, which amounts to about 160 million yen, and regard it as a proxy of the individuals’ average lifetime labor earnings.

Fig 7: Wives' intention for children's education attainment.

Fact 4. *Couples stop at fewer children than their ideal number primarily due to financial costs.*

This fact is drawn from the National Fertility Survey (NFS), which is provided by the National Institute of Population and Social Security Research (IPSS).⁴³ The NFS is a cross-sectional household survey that asks respondents about their preferences or intentions regarding fertility, marriage, child-raising, and education, as well as their basic information, including their education, age, and income. It is conducted nearly every five years, and the latest survey available is in 2015, which collected 5,334 couples in which the wife is aged 18 to 49. Hereafter, I present the results focusing on married couples in which the wife is aged 25 to 39 years, leaving 2,420 couples.⁴⁴ According to the NFS, a non-negligible gap exists between the ideal and planned numbers of children. In the 2015 survey, the ideal number of children for wives aged 25 to 39 was on average 2.38, whereas the planned number was 2.16. Fig 8 represents the distribution of the ideal and planned numbers of children, where blue (red) bars indicate the share of wives who desire (plan) to have each number of children from zero to more than five. This figure suggests that the gap originates from the downward revision of the ideal at the intensive margin. There is no significant share gap between those whose ideal number is zero and those whose planned number is zero, and a substantial fraction of wives who desire three children end up with one or two children.

⁴³See, https://www.ipss.go.jp/site-ad/index_english/survey-e.asp.

⁴⁴Its 53.1% of the sample consists of couples in which the wife is over age 40, so the sample size shrinks if we target the younger couples. I focus on wives under age 39 because here I am interested in the fertility intention of those in the stage of fertility decision. Note that the cohort fertility rate is stable after age 40 for any cohort in Japan. See, for example, p7 of <https://www.mhlw.go.jp/toukei/saikin/hw/jinkou/tokusyuu/syussyo07/dl/gaikyou.pdf> (in Japanese). Excluding those aged 18 to 24 does not affect the result significantly because they consist only of 1.5% of the observations for wives aged 18 to 49.

Fig 8: Distribution of ideal and planned numbers of children.

Fig 9: Reasons for the gap between the ideal and planned number of children.

Why do people abandon their ideal number of children? The NFS asks them to pick their reasons among several options, and the result indicates that they are most likely to choose the financial reason: “raising children and education are too expensive.” Fig 9 represents the likelihood⁴⁵ that wives of each age group abandon their ideal number of children for a particular reason, and “Financial” represents the financial reason. Aside from this, “Career” represents “it would interfere with my job,” and “Burden” represents “I would not handle the psychological and physical burden” (arising from achieving the ideal number). On average, more than 75% of them chose the financial reason, which dominates other reasons, such as “Career” and “Burden,” chosen by only 20% of them.

We observe the same even using the JPSC, which asks respondents about their preferences or intentions regarding fertility, such as “Do you want more children in the future?” If they answer “No,” it then asks the reasons from fourteen options, which they can choose multiple. The main options are: (1) having and educating children takes too much financial cost; (2) I would rather spend more time with my husband or for myself; (3) I want to continue my job; and (4) I cannot expect my husband’s effort in child-rearing. Fig 10 reports the likelihood for each of the four reasons, where I refer to (1), (2), (3), and (4) as *Financial*, *Time*, *Job*, and *Husband*, respectively. This figure indicates that more than 40% of parents cease reproduction due to the financial reason, which is the most important among other reasons.

⁴⁵I use the term “likelihood” instead of “share” because it allows respondents to choose multiple options.

Fig 10: Likelihood for reasons why parents cease reproduction. *Note:* Each of the four reasons, *Financial*, *Time*, *Job*, and *Husband*, represent: (1) having and educating children takes too much financial cost; (2) I would rather spend more time with my husband or for myself; (3) I want to continue my job; and (4) I cannot expect my husband’s effort in child-rearing.

To sum up, there is a non-negligible gap between the ideal and planned numbers of children for couples, and a substantial fraction of them answer the reason as “raising children and education are too expensive.” These results establish the first fact: couples are most likely to abandon having an ideal number of children because of financial costs.

Fact 5. *Children’s college enrollment is associated with a higher likelihood of parents stopping at fewer children due to the financial reason.*

This fact links the above four facts and suggests that college education costs are an important determinant of fertility choices in Japan. To see this, I conduct the following regression to examine the relationship between fertility *intentions* and children’s college enrollment:

$$\Pr(y_i = 1) = L(\alpha + \beta ChildCL_i + \mathbf{x}_i\boldsymbol{\theta} + \varepsilon_i),$$

Here, y_i is a dummy variable taking one if a couple i decides to stop having an additional child due to the financial reason. The results are summarized in Table 8.

	(1)	(2)
$ChildCL_i$	0.515*** (0.186)	0.870*** (0.222)
Personal characteristics	No	Yes
Observations	692	

Table 8: Children’s college enrollment and fertility intentions of women aged 24-39. *Note:* Values in parentheses represent standard errors. *** denotes statistical significance at the 1 percent level.

The first column presents the estimates where I control only for the children's college enrollment indicator. In the second column, I add couples' characteristics. The first and second columns report that the log odds ratio for couples choosing the financial reason to stop having children increases by 0.515 and 0.870 points for couples whose children will enroll in college. Both are statistically significant, and the latter implies a 2.4 times higher odds ratio for stopping having an additional child due to financial reasons.

D. More on Illustrative Model

D. (i) Derivation of Equation (2)

First, $cov(g(I; \varepsilon), V'(c(\varepsilon)))$ is negative because, for higher (lower) income levels, $g(I; \varepsilon) = (\mathbb{E}I - I) \cdot \varepsilon$ is higher (lower), whereas $V'(c(\varepsilon))$ is smaller (larger), leading to a negative value for covariance.

Next, I show that the following inequality holds:

$$\frac{\mathbb{E}V'(c(\varepsilon))}{\mathbb{E}V'(c(0))} \equiv \frac{\mathbb{E}V'(I - a(I; \varepsilon) \cdot n(\varepsilon))}{\mathbb{E}V'(I - a(I; 0) \cdot n(0))} < 1, \quad (10)$$

where $a(I; \varepsilon) = \underline{a} - g(I; \varepsilon)$ for some $\varepsilon \in \mathcal{E}$. (10) implies that

$$\mathbb{E}V'(c(\varepsilon)) < \mathbb{E}V'(c(0)).$$

To see this, recall that the subsidy $g(I; \varepsilon)$ is given as $g(I; \varepsilon) = (\mathbb{E}I - I) \cdot \varepsilon$, and let $\mathbb{E}V'(I - a(I; \varepsilon) \cdot n)$ denote the expected marginal utility from consumption as a function of the policy parameter ε , given the number of children n .

The first-order partial derivative with respect to ε , evaluated at $\varepsilon = 0$ (i.e., an economy without subsidy) is given as follows:

$$\begin{aligned} \left. \frac{\partial \mathbb{E}V'}{\partial \varepsilon} \right|_{\varepsilon=0} &= \mathbb{E}\{V''(c(0)) \cdot (\mathbb{E}I - I) \cdot n(0)\} \\ &= \underbrace{\mathbb{E}V''(c(0))}_{<0} \cdot \underbrace{\mathbb{E}(\mathbb{E}I - I) \cdot n(0)}_{=0} + cov(V''(c(0)), (\mathbb{E}I - I) \cdot n(0)) \\ &= cov(V''(c(0)), (\mathbb{E}I - I) \cdot n(0)) \\ &< 0, \end{aligned} \quad (11)$$

where $cov(V''(c(0)), (\mathbb{E}I - I) \cdot n(0))$ is negative because, with realization of higher (lower) income levels, V'' takes higher (lower) values because of the property $V''' > 0$, whereas $(\mathbb{E}I - I) \cdot n(0)$ takes lower (higher) values, and vice versa, for any $\varepsilon \in \mathcal{E}$. This implies that $\mathbb{E}V'(I - a(I; \varepsilon) \cdot n(\varepsilon))$ for any $\varepsilon \in \mathcal{E}$ is lower than $\mathbb{E}V'(I - a(I; 0) \cdot n(0))$, leading to the stated result.

D. (ii) Decomposing Direct Effects

Instead of the subsidy function $g(I; \varepsilon) = (\mathbb{E}I - I) \cdot \varepsilon$ in the illustrative model, I consider a new function $g(I; \psi, \tau) = 1/(\psi \cdot I) + \tau$, where ψ and τ are new policy parameters.

Let $n(\psi, \tau)$ be optimal fertility choices given policy parameters (ψ, τ) . Then, the effect of income-tested subsidy scheme, $g(I, \psi, 0)$, compared with an economy without subsidy, $g(I, 0, 0)$, can be expressed as follows:

$$\log \left(\frac{n(\psi, 0)}{n(0, 0)} \right) = \underbrace{\log \left(\frac{n(0, \tau)}{n(0, 0)} \right)}_{=\text{average effect}} + \underbrace{\log \left(\frac{n(\psi, 0)}{n(0, \tau)} \right)}_{=\text{insurance effect}}, \quad (12)$$

where a parameter τ satisfies a condition $\mathbb{E}g(I, \psi, 0) = g(I, 0, \tau)$ for a given $\psi \geq 0$. This condition means that the expected value of the subsidy is neutral between the income-tested subsidy scheme $g(I, \psi, 0)$ and the uniform subsidy scheme $g(I, 0, \tau)$. The average effect captures the effects of reducing the expected monetary costs of having children, while the insurance effect captures the effects of smoothing marginal utilities as discussed in the illustrative model, holding the expected value of the subsidy (i.e., the first moment) constant.

I use (12) to decompose the direct effect observed in the full quantitative model. In practice, I construct a grant function that provides the expected value of the cash transfers to each household, given the probability of the household being eligible for the subsidy. I then compute the effects of such uniform subsidy on fertility, which is the average effect. The insurance effect is then computed as the difference between the overall direct effect and the average effect.

E. Value Functions

Education Stage:

$$\begin{aligned} V_{g1}(a_{IVT}; h, I) &= \max_{c, l, a'} \{u(c, l) + \beta V_{g2}(a'; h, I)\}, \\ V_{g2}(a; h, I) &= \max_{c, l, a'} \{u(c, l) + \beta \mathbb{E}_{z_0} [V^w(a^s(a'), j = 22, z_0; e = 1, h)]\}. \end{aligned} \quad (13)$$

The budget constraints differ according to eligibility to the student loans. The budget constraints for eligible students are given as follows:

$$\begin{aligned} (1 + \tau_c)c + p_{CL} + a' &= (1 - \tau_w)w_{HS}(1 - \bar{t} - l) + \psi + \bar{g}(I) \\ &+ \begin{cases} (1 + (1 - \tau_a)r)a & \text{if } a \geq 0 \\ (1 + r^s)a & \text{otherwise} \end{cases} \\ a' &\geq -\underline{A}_s. \end{aligned} \quad (14)$$

The rest of the students cannot access to the student loans, which implies that their budget constraints are given as follows:

$$\begin{aligned} (1 + \tau_c)c + p_{CL} + a' &= (1 - \tau_w)w_{HS}(1 - \bar{t} - l) + \psi + \bar{g}(I) + (1 + (1 - \tau_a)r)a, \\ a' &\geq 0. \end{aligned}$$

College students must pay tuition fees p_{CL} . They can fund the consumption and tuition fees through (1) transfers from their parents a_{IVT} , (2) borrowing through student loans if

eligible, (3) government-provided grants if eligible, and (4) labor earnings by themselves. Students must spend a $\bar{t}$ fraction of their time on study while in college. Thus, they choose the time allocation between leisure and working over the disposable time $1 - \bar{t}$, where the total disposable time is normalized as 1. One unit of labor supply gives college students w_{HS} units of wages.⁴⁶ Following the literature, I assume that fixed payments are made for 20 years (10 periods) following college graduation and transform college loans into regular bonds according to the following formula:

$$a^s(a') = a' \times \frac{r^s}{1 - (1 + r^s)^{-10}} \times \frac{1 - (1 + r^-)^{-10}}{r^-}.$$

Early Working Stage: The remaining component of the value functions during the education stage, V^w , represents value functions in the early working stage (before fertility stage) for households aged $j \in \{J_E, \dots, J_F - 1\}$. The state variables for this stage consists of asset a , age j , idiosyncratic component of labor productivity z , education level e , and innate ability h . The uncertainty in this stage is only about the next period's productivity, which is denoted by z' following a Markov process $\pi_z(z', z)$. Households choose consumption, leisure, and savings given the state variables. The value function is formulated as follows:

$$\begin{aligned} V^w(a, j, z; e, h) = & \max_{c, l, a'} \{ u(c, l) \\ & + \begin{cases} \beta \mathbb{E}_{z'} [V^f(a', z', e, h)] & \text{if } j = J_F - 1 \\ \beta \mathbb{E}_{z'} [V^w(a', j + 1, z'; e, h)] & \text{otherwise} \end{cases} \} \\ \text{s.t.} & \\ & (1 + \tau_c)c + a' = (1 - \tau_w)w_e \eta_{j, z, e, h} (1 - l) + \psi + (1 + (1 - \tau_a)r)a, \\ & z' \sim \pi(z', z), \quad a' \geq -\underline{A}. \end{aligned} \tag{15}$$

Value functions V^f and V^r represent those for the fertility stage and retirement stage, which are formulated in the following subsections.

Late Working Stage: At this stage for households aged $j \in \{J_{IVT}, \dots, J_R - 1\}$, the value function is formulated as:

⁴⁶I assume that, while in college, there is no heterogeneity in labor efficiency and no uncertainty regarding the next period's productivity, and one unit of hours worked brings one unit of labor efficiency.

$$\begin{aligned}
V^w(a, j, z; e, h) &= \max_{c, l, a'} \{ u(c, l) \\
&\quad + \begin{cases} \beta[V^r(a', j+1)] & \text{if } j = J_R - 1 \\ \beta \mathbb{E}_{z'}[V^w(a', j+1, z'; e, h)] & \text{otherwise} \end{cases} \} \\
&\text{s.t.} \\
(1 + \tau_c)c + a' &= (1 - \tau_w)w_e \eta_{j, z, e, h}(1 - l) + \psi + (1 + (1 - \tau_a)r)a, \\
z' &\sim \pi(z', z), \\
a' &\geq \begin{cases} 0 & \text{if } j = J_R - 1, \\ -\underline{A} & \text{otherwise.} \end{cases}
\end{aligned} \tag{16}$$

Retirement Stage: At the beginning of age J_R , households are forced to retire from the labor market. After that, they spend all their time on leisure and make consumption-saving decisions. Two points differ from previous choice problems; they receive the pension benefit p from the government and face uncertainty about the next period's survival. The value function for the retirement stage is formulated as follows:

$$\begin{aligned}
V^r(a, j) &= \max_{c, a'} u(c, 1) + \beta \xi_{j, j+1} V^r(a', j+1) \\
&\text{s.t.} \\
(1 + \tau_c)c + a' &= p + (1 + (1 - \tau_a)r)a + \psi, \\
a' &\geq 0.
\end{aligned}$$

F. Equilibrium Definition

Let $\mathbf{x}_j^e$ be an age-specific state vector for agents with education level $e \in \{HS, CL\}$ and $\mu_j^e(\mathbf{x}_j^e)$ be the measure of agents with state vector $\mathbf{x}_j^e$. Let $I_l(h, I)$ and $I_g(h, I)$ be indicator functions for loans and grants, respectively, returning 1 if students with (h, I) are eligible and 0 otherwise.

Given exogenous parameters and policy rules $\{\tau_a, \tau_c, \iota, \iota_s, B, S, \psi, p, I_l(h, I), I_g(h, I)\}$, a *stationary recursive competitive equilibrium* consists of

- value functions $\{V_{g0}, V_{g1}, V_{g2}, V^w, V^f, V^{wf}, V^{IVT}, V^r\}$,
- policy functions for consumption, savings, leisure $\{c_j^e(\mathbf{x}_j^e), a_j^e(\mathbf{x}_j^e), l_j^e(\mathbf{x}_j^e)\}_{j=J_E}^J$, working hours $\{h_j^e(\mathbf{x}_j^e)\}_{j=J_E}^{J_R}$, fertility $\{n_{J_F}^e(\mathbf{x}_{J_F}^e)\}$, IVT $\{a_{J_{IVT}}^e(\mathbf{x}_{J_{IVT}}^e)\}$, and college enrollment $\{e_{J_E}(\mathbf{x}_{J_E})\}$,
- prices (r, w_{HS}, w_{CL}) ,
- labor income tax rate τ_w ,
- aggregate quantities (K, L_{HS}, L_{CL}) ,
- measures for households $\{\mu_j^e(\mathbf{x}_j^e)\}_{j=J_E}^J$,

such that:

1. The decision rules of students, workers, and retired households solve their problems, and $\{V_{g0}, V_{g1}, V_{g2}, V^w, V^f, V^{wf}, V^{IVT}, V^r\}$ are the associated value functions.
2. The representative firm maximizes its profit and optimally chooses capital and labor inputs:

$$r + \delta = \alpha \cdot Z \cdot \left(\frac{K}{L} \right)^{\alpha-1}, \quad (17)$$

$$w_{HS} = \tilde{Z} \cdot \omega_{HS} \cdot L_{HS}^{\chi-1}, \quad (18)$$

$$w_{CL} = \tilde{Z} \cdot \omega_{CL} \cdot L_{CL}^{\chi-1}, \quad (19)$$

where

$$L = [\omega_{HS} \cdot (L_{HS})^\chi + \omega_{CL} \cdot (L_{CL})^\chi]^{1/\chi},$$

$$\tilde{Z} = (1 - \alpha) \cdot Z \cdot \left(\frac{K}{L} \right)^\alpha \cdot [\omega_{HS} \cdot (L_{HS})^\chi + \omega_{CL} \cdot (L_{CL})^\chi]^{1/\chi-1}.$$

3. The labor market for each skill $e \in \{HS, CL\}$ clears:

$$L_e = \sum_{j=J_E}^{J_R} \int_{\mathbf{x}_j^e} \eta_j^e(\mathbf{x}_j^e) \cdot h_j^e(\mathbf{x}_j^e) d\mu_j^e(\mathbf{x}_j^e), \quad (20)$$

where $\eta_j^e(\mathbf{x}_j^e)$ represents the labor efficiency of agents with a state vector $\mathbf{x}_j^e$.

4. The capital market clears:

$$K = \sum_{j=J_E}^J \sum_e \int_{\mathbf{x}_j^e} a_j^e(\mathbf{x}_j^e) d\mu_j^e(\mathbf{x}_j^e). \quad (21)$$

5. The government budget is balanced:

$$\tau_c \cdot C + \tau_w \cdot (L_{HS} + L_{CL}) + \tau_a \cdot K + Q = p \cdot \mu_{old} + (\iota - \iota_s) \cdot K_s + G + \psi + B \cdot \mu_{j \leq 17} + S,$$

where

$$\begin{aligned}
C &= \sum_{j=J_E}^J \sum_e \int_{\mathbf{x}_j^e} c_j(\mathbf{x}_j^e) d\mu_j^e(\mathbf{x}_j^e), \\
Q &= \sum_{j=J_R+1}^J \frac{1 - \zeta_{j-1,j}}{\zeta_{j-1,j}} \sum_e \int_{\mathbf{x}_j^e} a_j^e(\mathbf{x}_j^e) d\mu_j(\mathbf{x}_j^e), \\
p \cdot \mu_{old} &= \sum_{j=J_R}^J \sum_e \int_{\mathbf{x}_j^e} p d\mu_j^e(\mathbf{x}_j^e), \\
K_s &= \int_{\mathbf{x}^s} \max\{0, -a^s(\mathbf{x}^s)\} \cdot I_l(h, I) d\mathbf{x}^s \\
G &= \int_{\mathbf{x}^s} g(h, I) \cdot I_g(h, I) d\mathbf{x}^s \\
B \cdot \mu_{j \leq 17} &= \sum_{j=J_F}^{J_{IVT}-1} \sum_e \int_{\mathbf{x}_j^e} B \cdot n d\mu_j^e(\mathbf{x}_j^e),
\end{aligned}$$

where $\mathbf{x}^s$, $\mu^s(\mathbf{x}^s)$, and $\{a^s(\mathbf{x}^s)\}$ represent a state vector for college students, measure of college students, and students' policy function for saving, respectively.

6. Distributions (measures) and households' behavior are consistent.

G. Computational Algorithm

G. (i) Stationary Equilibrium

For any variable or distribution x , let $\tilde{x}$ and $\hat{x}$ represent its guessed and model-implied values. Also, let μ_j represent the distribution over state variables for age j . Dividing the computation process into three blocks makes it easier to understand. The first block is the outer loop, searching for equilibrium prices. The other two blocks are inner loops; one is the *optimization block*, solving household problems given prices, and another is the *distribution block*, searching for the stationary distributions given prices and policy functions obtained in the optimization block. The computational algorithm proceeds as follows:

1. Guess prices $\tilde{\mathbf{p}} = (\tilde{r}, \tilde{w}_{HS}, \tilde{w}_{CL})$.

2. *Optimization block*:

- Guess the value function for agents at the beginning of age $j = 18$ ($\tilde{V}_{g0}$).
- Given $\tilde{V}_{g0}$, solve backward from the period of IVT choice to that of the education choice, which gives the model-implied value function for V_{g0} , $\hat{V}_{g0}$.
- Check if

$$d(\tilde{V}_{g0}, \hat{V}_{g0}) < \varepsilon, \quad (22)$$

where $d(\cdot)$ and $\varepsilon > 0$ represent an arbitrary metric function and error tolerance. If (22) is not satisfied, update $\tilde{V}_{g0}$ and follow the same procedure until

convergence. The correct V_{g0} pins down all value functions and policy functions given a set of prices $\tilde{\mathbf{p}}$.

3. *Distribution block*:

- Guess the distribution for age J_{IVT} . This $\tilde{\mu}_{J_{IVT}}$ and policy functions for IVT derive the implied distribution for agents aged 18, $\hat{\mu}_{18}$. Given $\hat{\mu}_{18}$ and policy functions, compute the implied distributions for age $j = 19, \dots, J_{IVT}$, and obtain $\hat{\mu}_{J_{IVT}}$.

- Check if

$$d(\tilde{\mu}_{J_{IVT}}, \hat{\mu}_{J_{IVT}}) < \varepsilon. \quad (23)$$

If (23) is not satisfied, update $\tilde{\mu}_{J_{IVT}}$ and follow the same procedure until convergence.

- After obtaining the correct distributions for age $j = 18, \dots, J_{IVT}$, compute the distribution for age $j_{IVT} + 1$ onward, using those distributions and policy functions.
4. After computing value functions, policy functions, and distributions, compute the implied quantities, $\hat{L}$ and $\hat{K}$ based on (20) and (21), which gives the implied prices $\hat{\mathbf{p}}$ based on $\hat{L}$, $\hat{K}$, (17), (18), and (19).
5. Check if

$$d(\tilde{\mathbf{p}}, \hat{\mathbf{p}}) < \varepsilon. \quad (24)$$

If (24) is not satisfied, update $\tilde{\mathbf{p}}$, return to the optimization block, and follow the same procedure until convergence.

G. (ii) Transition Dynamics

For any variable or distribution x , let $\tilde{x}$ and $\hat{x}$ represent its guessed and model-implied value (or distribution). Also, let $\mathbf{q}_t = (K_t, L_t)$ be a vector of aggregate quantities in a year t , and $\mathbf{q} = (\mathbf{q}_t)_{t=1, \dots, T}$ for some T . The computational algorithm for transition dynamics proceeds as follows:

1. *Preliminaries*: Set an arbitrarily large number for transition periods, T . Given aggregate quantities in the initial and final steady states, $\mathbf{q}_1$ and $\mathbf{q}_T$, guess a sequence of aggregate quantities, $\{\tilde{\mathbf{q}}_t\}_{t=1, \dots, T}$, where $\tilde{\mathbf{q}}_1 = \mathbf{q}_1$ and $\tilde{\mathbf{q}}_T = \mathbf{q}_T$, which pins down guesses for prices $\{\tilde{r}_t, \tilde{w}_t\}_{t=1, \dots, T}$. Also, guess a sequence of the labor income tax rate $\{\tilde{\tau}_{l,t}\}_{t=1, \dots, T}$, where $\tilde{\tau}_{l,1}$ and $\tilde{\tau}_{l,T}$ are the tax rates at the initial and final steady states.
2. *Optimization*: Given $\{\tilde{r}_t, \tilde{w}_t\}_{t=1, \dots, T}$ and $\{\tilde{\tau}_{l,t}\}_{t=1, \dots, T}$, solve the optimization problem for each cohort born before period T .
3. *Distribution*: Given decision rules for each cohort obtained in the above optimization block, construct the implied distributions:

- $\tilde{\mu}_a(j; t)$: (aggregate) savings distribution across age in year t .

- $\tilde{\mu}_n(j; t)$: (aggregate) labor supply distribution across working-age in year t .
 - $\tilde{\mu}_{j|t}$: age distribution in year t .
4. Given the decision rules and the implied distributions, compute the model-implied aggregate quantities, $\hat{\mathbf{q}}$. Also, compute the implied government revenue and expenditures, denoted by $\hat{\mathbf{G}}_r = (\hat{\mathbf{G}}_{r,t})_{t=1,\dots,T}$ and $\hat{\mathbf{G}}_e = (\hat{\mathbf{G}}_{e,t})_{t=1,\dots,T}$.
 5. Check if

$$d(\tilde{\mathbf{q}}, \hat{\mathbf{q}}) < \varepsilon$$

and

$$d(\hat{\mathbf{G}}_r, \hat{\mathbf{G}}_e) < \varepsilon.$$

If the first (second) condition is not satisfied, update $\tilde{\mathbf{q}}$ ($\{\tilde{\eta}_{l,t}\}_{t=1,\dots,T}$) and follow the same procedure until convergence.

H. More on Calibration and Validation

H. (i) Stochastic income process

I estimate the AR(1) process for college graduates and high school graduates separately, following the procedure of [Darulich and Kozłowski \(2020\)](#). First, I control for the age component for each education level, $\gamma_{j,e}$, and obtain the residual $u_{i,j,e}$ for an individual i aged j with education level e , which is considered the sum of two components as follows:

$$u_{i,j,e} = m_{i,j,e} + z_{i,j,e}.$$

The measurement error $m_{i,j,e} \sim N(0, \sigma_e^m)$ is normally distributed with mean 0 and variance σ_e^m , and $z_{i,j,e}$ is a persistent shock that follows an AR(1) structure:

$$\begin{aligned} z_{i,j,e} &= \rho_e^z z_{i,j-1,e} + \epsilon_{i,j,e} \\ \epsilon_{i,j,e} &\sim N(0, \sigma_e^z). \end{aligned}$$

The initial draw for z , $z_{i,0,e}$, follows $N(0, \sigma_e^{z_0})$. I estimate this process for each education group using a Minimum Distance Estimator, using covariances of wage residuals at various lags for different age groups as moments.

H. (ii) Education subsidy elasticity of fertility

The regression equation for the education subsidy elasticity of fertility, discussed in Section [D.\(iii\)](#), is given as follows:

$$\log(\text{Fertility}_{i,t}) = \alpha + \beta \text{Spending}_{i,t} + \mathbf{x}'_{i,t} \boldsymbol{\gamma} + \zeta_t + \eta_i + \varepsilon_{i,t},$$

where $\text{Spending}_{i,t}$ is the government spending on tertiary education (per student / GDP per capita $\times 100$) in country i and year t , and $\mathbf{x}'_{i,t}$ includes GDP per capita, Gini coefficient,

government expenditures on other education stages, and population share of working-age population. The estimation results are summarized in Table 9.

	(1)	(2)
Spending _{<i>i,t</i>}	$2.7e - 04^{***}$ ($7.5e - 05$)	$1.3e - 03^*$ ($7.6e - 04$)
Sample	Full	OECD
Observations	456	201

b_4	0.56	Share of four or more children	0.02	0.00
Z	1.99	High school graduates' wage	1.0	1.0

Table 12: Parameters internally determined. *Note:* “HS” and “CL” indicate high school and college graduates.

H. (iv) Non-targeted Moments

This subsection shows that the benchmark model replicates several moments not targeted in calibration, such as fertility differentials and fertility elasticities.

D.(i) The fertility differential across education levels

More educated parents have fewer children than less educated parents; according to my sample of the JPSC, the completed fertility of college graduates was 1.92, which is lower than the 2.12 for their high school graduate counterparts.⁴⁷ In this benchmark model, the completed fertility of college graduate wives is 1.79, which is lower than the high school graduate wives', 2.28. The benchmark model captures the fertility differential across education levels with a similar degree.

Why does this fertility differential result in this model? First, the opportunity costs of having children are more significant for college graduates, making child-bearing more costly for them. Second, college graduate parents are more willing to pay for the IVT, making a child more costly. This is because the children's innate ability and psychic costs

⁴⁷This is also observed in the National Fertility Survey (NFS) provided by the National Institute of Population and Social Security Research (IPSS), another data source where we can check the completed fertility rate by different education levels. See, https://www.ipss.go.jp/site-ad/index_english/survey-e.asp. According to the NFS (2015), college graduate wives' completed fertility has been lower than less educated ones almost every survey year since 1977. The latest survey in 2015 reports that the completed fertility of wives with a college degree was 1.89, and that of high school graduate wives was 1.98.

of education, (h_k, ϕ_k) , govern education returns and the willingness to attend college, which in turn governs the marginal gains from IVT for parents.

Appendix A. presents simple static models that highlight these mechanisms in closed forms. These two mechanisms align with the major explanations proposed by the theoretical literature on the fertility differentials across income distribution:⁴⁸ (1) having children is more costly for higher-income households, provided that having children is time-intensive, and (2) higher-income households have higher demands for child quality or an advantage in parental investments.

D.(ii) The benefit elasticity of fertility

Previous studies show that cash benefits such as the child benefit and baby bonus have a significant impact on fertility. Many of them report that the benefit elasticity of fertility, the percentage increase in fertility rate against the one percent increase in the cash transfer, is about 0.1 – 0.2. For example, Milligan (2005) studies a reform of Quebec’s baby bonus and shows that an extra 1,000 Canadian dollars benefit would increase fertility by 16.9%, which implies a benefit elasticity of 0.107. Cohen, Dehejia, and Romanov (2013) uses a variation in the child subsidy payment observed around 2003 in Israel, providing a larger subsidy for third or higher births. They show that the benefit elasticity of fertility was 0.176. González (2013) adopts the regression discontinuity design to study the effects of Spain’s reform in 2007, introducing a one-time payment of 2,500 euros (about 3,800 USD) for births, almost 4.5 times the monthly minimum wage for full-time workers. It finds a statistically significant impact on fertility, increasing conceptions by 5 – 6%.

To examine how this model performs in this respect, I conduct the following exercise. Let B_0 denote the per-child cash transfers for households with children under 17 in the benchmark. I solve the household problem, holding prices, tax rate, and distribution fixed, with several levels of the per-child payment $B = B_0 \cdot (1 + x)$ for some $x \in X$, where X is a set of positive real numbers. This procedure brings the implied fertility rate, and with the expansion rate x , we can compute the implied benefit elasticity of fertility for the case of the expansion rate x . I set $X = \{0.1, 0.2, \dots, 1.9, 2.0\}$, which is a reasonable range in the context of the expansion examined in the empirical studies, and compute the implied elasticity for each x . Then, I take the average of those 20 values. I find that the average elasticity is 0.138 (with a standard deviation of 0.025), which is consistent with the empirical estimates.

D.(iii) The education subsidy elasticity of fertility

The model also replicates the cross-country estimate of the relationship between total fertility rates and the “generosity” of the higher education subsidy measured by the government expenditures on higher education per student relative to the country’s GDP per capita. I use cross-country panel data from the World Bank,⁴⁹ collecting more than 200 countries/regions over more than 50 years. I then regress the log of total fertility rates of a country i in year t on the generosity of the subsidy for the same country-year, controlling for country-fixed effects, time-fixed effects, and other covariates such as GDP per capita

⁴⁸See, for example, Jones, Schoonbroodt, and Tertilt (2010).

⁴⁹See, <https://databank.worldbank.org/>.

and demographic factors. I call the estimated coefficient for the generosity of the subsidy *education subsidy elasticity of fertility*, which indicates a one percentage point increase in government spending on higher education—per student relative to GDP per capita—is associated with what percent of the total fertility increase.

Based on the sample of the OECD countries, the estimated coefficient is 0.0013, which is marginally significant (at 10% level). Based on the sample of the entire set of (more than 200) countries/regions, the estimated coefficient is 0.00027, which is statistically significant at the 1% level. I simulate an introduction of a uniform subsidy using the benchmark model by providing uniform cash transfers—that amount to 1% of the GDP per capita—to all college students. This simulation leads to a 0.11% increase in total fertility, which aligns with the estimate based on the OECD countries. The details of the regression analysis are relegated to Appendix H. (ii).

D.(iv) Composition of students’ revenue

Capturing the composition of students’ revenue—how college students finance their living expenses and tuition fees—is also important as it is critical not only to students’ education choices but also to parents’ IVT choices and, thereby, fertility choices. According to the SLS (2018), the students’ revenue consists of three parts. First, the greatest part, 61% of their revenue, is accounted for by asset transfers from their parents. Second, students’ labor earnings account for 21%, and lastly, the rest (18%) is financed by student loans. Although the revenue share of labor earnings (21%) is a targeted moment, the rest is not targeted. As Table 13 shows, the model captures the overall revenue composition as well. The IVT and loans account for 66% and 14% of their revenue, close to the data counterparts.

	IVT	Loan	Labor
Data	0.61	0.18	0.21
Model	0.66	0.14	0.20

Table 13: Composition of Students’ Revenue.

I. On the Welfare Analysis

The welfare analysis using models with endogenous fertility is not straightforward theoretically and philosophically. One of the well-known difficulties in the economics or theoretical context is that the standard concept of Pareto efficiency is not applicable to models with endogenous fertility (Goloso, Jones, and Tertilt, 2007).⁵⁰ Given that the literature on the normative analysis of endogenous fertility models is still developing and

⁵⁰This is because models with endogenous fertility require a welfare comparison between two different sets of individuals. Goloso, Jones, and Tertilt (2007) then propose two efficiency concepts that can apply to models with endogenous fertility. For example, the $\mathcal{A}$ -efficiency proposed by them focuses on individuals being alive in both economies. This concept is particularly beneficial if we examine the optimal policy as they show that the unique solution for the planning problem considering the utility of the existing agents (i.e., those who are alive just before the policy is introduced) corresponds to the $\mathcal{A}$ -efficiency.

there is no one “correct” method to tackle this issue (at least for now), this study captures the welfare effects of the policy by the consumption equivalence under the veil of ignorance under the benchmark economy relative to the new steady state.⁵¹

To formalize the measure, let $P \in \{0, 1, 2, \dots\}$ denote education subsidy schemes or policies with $P = 0$ representing the benchmark economy without grants. Next, let $V^P(\lambda)$ be the expected lifetime utility in stationary equilibrium for newborn agents with a consumption scaling parameter λ and policy P :

$$V^P(\lambda) = \int_{\mathbf{x}_1} V_{j=1}^P(\mathbf{x}_1; \lambda) d\mu(\mathbf{x}_1). \quad (25)$$

$\mu(\mathbf{x}_j)$ is the measure over the age-specific state space where $j \in \{1, \dots, J\}$ and $V_{j=1}^P(\mathbf{x}_1; \lambda)$ represents the expected utility for an agent aged $j = 1$ with a state vector $\mathbf{x}_1$:

$$V_{j=1}^P(\mathbf{x}_1; \lambda) = \mathbb{E} \left\{ \sum_{j=1}^J \beta^{j-1} \cdot u(c_j \cdot (1 + \lambda), l_j) + \sum_{j=J_F}^{J_{IVT}-1} \beta^{j-1} b(n) \cdot v(q_j) + \beta^{J_{IVT}-1} \lambda_a \cdot b(n) \cdot V_{g0}(\mathbf{x}_{J_{IVT}}) \right\}$$

Here, $\{c_j, l_j, q_j, n, a_{IVT}\}$ are optimal choices with the policy P and each state $\mathbf{x}_j$. Finally, the consumption equivalence with a policy P is given as a scalar λ satisfying the following equation:

$$V^0(\lambda) = V^P(0).$$

That is, the consumption equivalence λ makes the newborn agents indifferent between the new economy and the benchmark by scaling up the benchmark consumption by λ .

J. Decomposing the Long-run Effects

The long-run increases in fertility, college enrollment rates, output, and welfare can be broken down into direct effects and indirect effects. The direct effects capture the effects of introducing the policy holding macroeconomic objects—such as prices, tax rates, and distributions—fixed and can be further broken down into the insurance effect and average effect. The indirect effects capture the effects of the policy induced by changes in factor prices (i.e., GE effects), tax rates (i.e., Taxation effects), and household distribution (i.e., Distributional effects). To isolate each effect, I conduct a decomposition exercise as follows. I first solve an equilibrium by introducing the new grant function. Then, I solve household problems by replacing one of the four objects (grant function, prices, tax rate, and household distribution) in the benchmark with that in the new equilibrium. Note that this method does not guarantee that each implied effect adds up to the overall effects because all factors except grant function are endogenous and interconnected; however, my results indicate that each effect adds up roughly to the overall effects. I further decompose

⁵¹The related work [Zhou \(2022\)](#) adopts the same welfare criteria in its steady-state analysis. In its transition analysis, [Zhou \(2022\)](#) also computes the average welfare of the existing households already alive before the policy changes to evaluate the $\mathcal{A}$ -efficiency of the policy.

the direct effects into the insurance and average effects based on the method discussed in Section D. (ii). Tables 14 and 15 summarize the decomposition results.

	Direct		Indirect			All
	Average	Insurance	GE	Tax	Dist.	
TFR (Δ %)	+0.8	+1.3	+1.0	0.0	-1.0	+3.1
HS (Δ %)	+0.1	+0.8	0.0	0.0	0.0	-0.3
CL (Δ %)	+2.4	+2.1	+2.4	0.0	0.0	+10.5

Table 14: Decomposition results. *Note:* Columns “Direct,” “GE,” “Tax,” and “Dist.” report the results when only grant function, prices, labor income tax rate, and distribution change, respectively. A column “All” indicates the results in the benchmark and the long-run equilibrium with the grants. Rows “CL share” represent the change in college enrollment rate in p.p. and rows “HS” and “CL” represent the percentage changes in fertility rates for high school and college graduates.

Fertility: For the long-run increase in the TFR, vital forces are direct and GE effects. If the grant is introduced while other variables are fixed as in the benchmark, the TFR increases by 2.1% (direct effects), which corresponds to two-thirds of the overall effects.

The GE effect also plays a role in accounting for the TFR increase. If the prices are set to the long-run equilibrium levels while other objects are fixed as in the benchmark, the college graduates’ fertility increases by 2.4%, and the TFR then increases by 1.0%. The key is the decline of the wage rate for college graduate workers, w_{CL} . In the long-run equilibrium with the grants, w_{CL} decreases by 2.2%. First, the greater supply of college graduate workers depress w_{CL} relative to w_{HS} . In addition, greater aggregate labor supply in efficiency units and lower capital accumulation discussed in Section ?? imply the lower marginal productivity of labor, decreasing w_{CL} . The lower w_{CL} implies the lower opportunity costs of having children for college graduates, making some have more children. Also, for college graduate parents, the lower w_{CL} reduces the (expected) utility of the IVTs, given that their children are likely to attend college, as discussed above. The lower utility of the IVTs also contributes to higher fertility because the marginal utility gains from investing in children’s “quality” (by making IVTs to send a child to college) are relatively lower than those from increasing its “quantity.”⁵²

Lastly, the distribution effect implies a 1.0% decline in the average fertility. The introduction of the grants increases the college enrollment rate, meaning that the share of college graduates increases in the long run. Given that college graduates have fewer children than high school graduates as discussed in Section D.(i), the greater share of college graduates means a greater share of those who tend to have fewer children, which can lead to a lower average fertility.⁵³ However, direct and GE effects are significant and lead to the higher TFR.

⁵²This fertility response of college graduates to the change in skill premium aligns with an empirical observation (Lehr, 2003).

⁵³This effect is comparable with a composition effect highlighted by Zhou (2022) in understanding the effects of public education subsidies on fertility. In his model, in the long run, public education subsidies increase the share of parents with higher human capital, who tend to have fewer children.

	Direct	GE	Tax	Dist.	All
CL share (Δ p.p.)	+2.5	-0.1	0.0	+2.2	+3.9
Output (Δ %)	-0.7	-0.1	-0.1	+1.4	+1.0
Welfare (%)	+2.6	-0.7	-0.2	+2.3	+5.1

Table 15: Decomposition results. *Note:* Columns “Direct,” “GE,” “Tax,” and “Dist.” report the results when only grant function, prices, labor income tax rate, and distribution change, respectively. A column “All” indicates the results in the benchmark and the long-run equilibrium with the grants. Welfare gains are represented in terms of consumption equivalence.

College Enrollment: For the long-run increase in the college enrollment rate, critical forces are direct and distribution effects. If the grant is introduced while other variables (i.e., prices, tax rate, and distribution) are fixed as in the benchmark, the college enrollment rate increases by 2.5 p.p., more than half of the overall increase. These direct effects capture the effects of relaxing financial constraints on college enrollment decisions. GE effects put downward pressure on college enrollment because the lower college premium reduces the incentive for college enrollment.

Note that these direct effects do not explain the overall effects, so we need other forces accounting for the increase in college enrollment rate; that turns out to be the distribution effects. The implied changes in the distribution in the long run, holding grant function, prices, and tax rate fixed as in the benchmark, lead to a 2.2 p.p. higher college enrollment rate. The most relevant factor is the change in the skill distribution of parents (i.e., the share of college graduates). The increase in the share of college graduates implies a higher share of those more likely to have children enrolling in college due to the intergenerational persistence of education. Then, the distributional change amplifies the short-run increase in college enrollment rate facilitated by the direct effects.

Output: The distribution effect is critical in accounting for the output increase. In the long run, the working-age population increases due to a higher equilibrium TFR, and the share of skilled workers increases. These forces increase the labor supply in efficiency units, increasing output in the long run.

In contrast, the direct and GE effects put downward pressure on output. As indicated in Table 15, the GE effects lower the college enrollment rate due to the reduced skill premium. The resulting lower share of skilled workers leads to a lower output.

Next, recall that the direct effect can be considered the short-run effect of the introduction, where other macroeconomic variables, such as prices, tax rates, skill distribution, and age distribution, are fixed as in the benchmark. In the short run, aggregate savings and labor supply decrease due to higher fertility; having a child requires parents to spend a fraction of their time and some additional money, reducing their working hours and savings. Thus, the aggregate output decreases in the short run.

Welfare: The direct effect explains more than half of the welfare gains. Importantly, introducing the grants makes agents attend college with smaller costs and enables someone who could not attend college in the benchmark to do that, bringing them a higher lifetime income. The rest of the gains are explained by the distribution effect. The education subsidy increases the share of college graduates in the long run, and the lifetime

utility for college graduates is, in principle, greater than that for high school graduates, particularly because of their higher income due to the college education returns. Thus, this distributional change increases the expected lifetime utility. Note that the direct effect is about the change in $V_{j=1}^P$ in equation (25), while the distribution effect is about the change in μ there.

K. Expansion

In this section, I consider the effects of raising the income threshold $\bar{I}$ so that students in households of broader income classes can be eligible. Recall that I set the threshold $\bar{I}$ so that the existing grants target the students in households at the bottom 15 % of the income distribution. In this experiment, I increase $\bar{I}$ so that it corresponds to the 40, 50, and 60 percentiles of the income distribution and solve the stationary equilibrium in each case. For students in the household at the bottom 15 %, the payment is still given by g , which amounts to two-thirds of the average expenses of students in the benchmark. For students in households higher than the 15 percentile but less than x percentile of the income distribution, where x takes either 40, 50, or 60, the payment is given by $g/2$, which amounts to one-third of the average expenses of students. In other words, the payment tapers off in income. Letting $\bar{I}_{15\%}$ and $\bar{I}_{x\%}$ denote the income level of 15 and $x \in \{40, 50, 60\}$ percentiles of the income distribution, the grant function $g(h, I; x)$ with a threshold $\bar{I}_{x\%}$ can now be formulated as:

$$\bar{g}(I; x) = \begin{cases} g & \text{if } I < \bar{I}_{15\%} \\ g/2 & \text{if } I \in [\bar{I}_{15\%}, \bar{I}_{x\%}) \\ 0 & \text{otherwise} \end{cases} \quad (26)$$

Table 16 summarizes the results, and there are several takeaways there. First, the equilibrium college enrollment increases as the income threshold is higher. Setting the threshold at the 40, 50, and 60 percentiles of the income distribution, the enrollment rate increases by 4.7 p.p., 5.6 p.p., and 6.2 p.p., respectively, in stationary equilibrium. This is also the case for educational mobility and labor income tax rates. The expansion requires additional revenue, so the equilibrium tax rate should also increase by 0.3 p.p. for the case of the 60% threshold.

However, the expansion would not significantly increase the TFR. Recall that the introduction leads to a 3% increase in TFR, from the benchmark level of 2.096 to 2.160 in the long-run equilibrium with the grants. With grant functions $g(h, I; 40)$, $g(h, I; 50)$, and $g(h, I; 60)$, the equilibrium TFR would be 2.158, 2.151, and 2.157, respectively; the TFR even decreases locally with expansion. Fertility rates for each skill help us understand this situation. First, college graduates continue to increase fertility. With grant functions $g(h, I; 40)$, $g(h, I; 50)$, and $g(h, I; 60)$, their equilibrium fertility rate would be 1.996, 1.998, and 2.021, all higher than the fertility rate with the existing grants, 1.978. This result is straightforward to understand given that the insurance and GE effects contribute to the fertility increase of college graduates when the grants are introduced, as discussed in Section J.. On the contrary, fertility among high school graduates decreases with expansion, making the TFR remain almost constant even though fertility among college graduates increases. Fig 11 depicts the changes in the TFR and fertility rates for high

school and college graduates, where the equilibrium TFR with the existing program (with the 15 percentile threshold) is normalized to one.

	<u>Threshold</u>			
	15%	40%	50%	60%
CL share (Δ p.p.)	+3.9	+4.7	+5.6	+6.2
HS→CL (Δ p.p.)	+2.5	+2.6	+3.1	+3.3
Tax (Δ p.p.)	+0.02	+0.17	+0.23	+0.30
Output ($\Delta\%$)	+1.0	+1.3	+0.2	-0.5
Welfare (%)	+5.1	+6.5	+6.3	+5.5

Table 16: Main results of higher income thresholds. *Note:* Rows “CL share” and “HS→CL” represent the changes in college enrollment rate and educational mobility in the sense of probability that children of high school graduates attend college. Output changes are expressed as percentage changes. Changes in college enrollment rate, educational mobility, and tax rate are represented as changes in percentage points. Welfare gains are represented in terms of consumption equivalence.

Fig 11: Changes in fertility rates with expansion. *Note:* The equilibrium TFR with the existing program (with the 15% threshold) is normalized to one. “HS” and “CL” represent fertility rates for high school and college graduates.

Why do high school graduates decrease fertility as the income threshold is higher? To understand this, I conduct the decomposition when the grant function is given by $g(h, I; 60)$, and the results are summarized in Table 17. Two effects are critical to explain the fertility decreases of high school graduates: the direct and GE effects.

In this case with the grant function $g(h, I; 60)$, the wage rate for high school graduates, w_{HS} , is 0.6% higher in the long run than in the benchmark, especially because of the significant supply of college graduates. This higher wage rate makes the opportunity costs of having children for high school graduates higher, which puts downward pressure on their fertility rates.

Next, the direct effects imply a lower fertility rate for high school graduates. This result is somewhat confusing given that we discuss the insurance effects of the grants on fertility, which is critical to account for the fertility increases of college graduates. Why do the

direct effects lead to lower fertility for high school graduates? In the benchmark without grants, children of high school graduates are unlikely to attend college. If the grants are introduced and their target expands, educational mobility increases in the sense that children of high school graduates are more likely to attend college than in the benchmark, as represented in Table 16. Given that the grants are not generous enough to cover 100% of the costs to send their children to college, this higher probability of children going to college implies that those parents are more likely to have to make additional transfers upon children’s college enrollment. The expansion thus increases the expected costs of children for high school graduates, which lowers their fertility.

	Direct	GE	Tax	Dist.	All
HS ($\Delta\%$)	-0.7	-1.4	0.0	0.0	-0.8
CL ($\Delta\%$)	+9.1	+4.3	+2.4	+0.6	+13.2

Table 17: Decomposing the effects on fertility with $g(h, I, 60)$. *Note:* Rows “HS” and “CL” represent the percentage changes in fertility rates for high school and college graduates.

Last, the output increases in expansion up to the case of the 40 percentile threshold, but they start declining after that point, as Table 16 and Fig 12 indicate. If the income threshold becomes sufficiently high, households with children have less incentive to save to support their college enrollment because they will likely be eligible for the grants. This higher probability of eligibility also causes an income effect on labor supply. Thus, the aggregate capital and labor supply decrease when the income threshold becomes sufficiently high, reducing the output. This concavity of output gains with expansion applies to the welfare gains. The marginal utility gains of the grants decrease in the values of the income threshold while the tax rate increases with expansion. Then, the net gains start declining at some point.

Fig 12: Changes in aggregate output, capital, and labor supply in efficiency unit with expansion. *Note:*

L. Reallocating Resources to Different Programs

This section examines the performance of the potential alternative programs to the existing income-tested grants. To this end, I consider another two scenarios, in addition to the

introduction of income-tested grants to the benchmark model, examined in Section ??.

The first scenario is to introduce grants for college students with income and ability tests so that “high-ability” students in poor households are eligible. More specifically, I keep the income threshold adopted in the existing scheme but arbitrarily set the lower bound for students’ innate ability for the eligibility, $\underline{h}$, to its median. The payment function $g(h, I)$ for this scheme is defined as follows:

$$g(h, I) = \begin{cases} g_1 & \text{if } I < \bar{I} \text{ \& } h > \underline{h} \\ 0 & \text{otherwise} \end{cases}$$

Here, the payment g_1 is set so that the short-run expenditure upon the introduction is the same as that of the existing income-tested grants. As a result, g_1 covers approximately 100% of the average student’s expenditure in the benchmark, which is greater than the payment in the existing scheme with only income tests because the number of eligible students is fewer.

The second scenario introduces unconditional grants for college students regardless of ability and income. The payment function is given as $g(h, I) = g_2$ for any students with (h, I) , where g_2 is set so that the short-run government expenditure is the same as the existing program. As a result, g_2 covers approximately 10% of the average students’ expenditure in the benchmark, which is less significant than in the existing income-tested grants because this alternative program covers a broader range of students.

I solve the stationary equilibrium with each scenario, and the results regarding fertility and enrollment rates are summarized in Table 18. A highlight is that the existing scheme with income tests would lead to the highest equilibrium TFR among other scenarios. Notably, the unconditional grants lead to a 1.2 p.p. higher college enrollment rate than the income-tested ones and a -0.3% lower TFR because of the composition effect. These results highlight the insurance effect of the income-tested grants on fertility and the downward pressure the grants exert on aggregate fertility through composition changes.

	Income	+Ability	Uncond.
CL share (Δ p.p.)	+3.9	+2.6	+5.1
TFR ($\Delta\%$)	+3.0	+2.7	-0.3
HS	+0.4	-3.5	+4.0
CL	+7.4	+8.4	+3.9
Output ($\Delta\%$)	+1.0	-0.1	-0.7
STD (wage) ($\Delta\%$)	-1.3	-0.9	-0.1
Welfare ($\%$)	+5.1	+2.6	+1.6

Table 18: Main results with several schemes with different targets. *Note:* values in each cell indicate changes from the benchmark value. Rows “HS” and “CL” indicate the percentage changes in the fertility of high school and college graduates.

M. Comparison With Pro-natal Transfers: Macroeconomic Effects

This section examines the differences in the macroeconomic implications between the education subsidy and child benefit (i.e., typical pro-natal cash transfers).⁵⁴ To this end, I simulate the expansion of the unconditional cash transfers to households with children B from its benchmark value while setting $\bar{g}(I) = 0$ for any I as in the benchmark. The new level of the per-child payment B is set so that the short-run expenditure upon the introduction is the same as that of the existing income-tested grants, which leads to a 6.5% increase in the per-child payment.

I solve the stationary equilibrium with the expansion of the per-child payment B , and the main results are summarized in Table 19. Columns “Education” and “Typical” represent the results of the introduction of income-tested grants and the expansion of child benefit (“typical” pro-natal transfers).

The child benefit expansion leads to a 2.5% increase of the TFR in the long-run equilibrium, comparable to introducing the income-tested grants but slightly lower than that. The previous decomposition analysis suggests that targeting students in unlucky households in which negative income shocks are realized would be effective, at least marginally, in increasing the TFR. A notable observation is that the characteristics of households who respond to the policy differ between the two cases; the education subsidy induces skilled households to have more children, while the child benefit has a similar degree of impact on skilled and unskilled households regarding fertility. This is because the former is more beneficial for households whose potential children are likely to attend college, and college graduates tend to be those households due to the intergenerational persistence of education.

The college enrollment rate does not change in response to the child benefit expansion. The expansion also does not affect the average human capital, defined as the workers’ average of labor efficiency $\eta_{j,z,e,h}$,⁵⁵ while the education subsidy increases the average human capital by 1.0% primarily because of the higher college enrollment rate. The difference in the average human capital also leads to the difference in the per-capita output. While the education subsidy increases the per-capita output by 1.0% in the long run, the child benefit expansion would rather lead to a 0.3% lower per-capita output. As in the case of introducing the education subsidy, the child benefit expansion also leads to lower (physical) capital accumulation due to crowding out and demographic change, as discussed in Section ???. The education subsidy has sufficiently large positive effects on aggregate labor supply in efficiency units, which surpasses the negative impacts on physical capital accumulation and increases output. The child benefit expansion has more modest impacts on aggregate labor efficiency than the education subsidy, leading to the gap in output gains between the two policies.

The child benefit expansion does not affect the standard deviation of wages, whereas the education subsidy leads to a lower standard deviation by enabling some students in

⁵⁴In Section L., I also consider reallocating resources into different targets to implement the education subsidy by considering unconditional transfers to college students and introducing ability tests.

⁵⁵Formally, I define the average human capital as $\sum_j \int_{z,h} [(1-s) \cdot \eta_{j,z,e=0,h} + s \cdot \eta_{j,z,e=1,h}] dF(z,h) \mu_j$, where s represents the college enrollment rate, $F(z,h)$ represents the stationary distribution over (z,h) , and μ_j is the stationary distribution of age.

poor households to attend college and acquire skills. Lastly, the expansion leads to a 0.3% of the welfare gain, which is substantially lower than a 4.8% gain with the education subsidy. As discussed in Section ??, the welfare gains of the education subsidy come mainly from the higher expected lifetime income in each state and the higher probability of being college graduates and enjoying higher earnings facilitated by the higher college enrollment rate and educational mobility, as opposed to the child benefit expansion do. Thus, the education subsidy leads to greater welfare gains than the child benefit expansion under the veil of ignorance.

A caveat is that this model does not capture the endogenous human capital accumulation before high school graduation and the dynamic complementarity of human capital. Households may increase their investments in their children upon the child benefit expansion, which contributes to greater human capital; however, that channel is not considered in this current analysis. Those ingredients can be critical in comparing the effects of these different programs, especially on college enrollment rates, aggregate human capital, and output. The exercise in this framework is a first step, and incorporating those ingredients – fertility, college enrollment, dynamic complementarity of human capital– in one framework is left for future research.

	Education	Typical
TFR ($\Delta\%$)	+3.0	+2.5
HS	+0.4	+2.5
CL	+7.4	+2.4
CL share (Δ p.p.)	+3.9	0.0
HS→CL	+2.5	0.0
Avg. HC ($\Delta\%$)	+1.0	0.0
Output ($\Delta\%$)	+1.0	−0.3
STD (wage) ($\Delta\%$)	−1.3	0.0
Welfare (%)	+5.1	+0.3

Table 19: Main results with several schemes with different targets. *Note:* Columns “Education” and “Typical” represent the results with the introduction of the education subsidy and expansion of child benefit (“typical” pro-natal transfers), respectively. Values in each cell indicate changes from the benchmark value. Rows “HS” and “CL” indicate the percentage changes in the fertility of high school and college graduates. “HS→CL” represent the changes in college enrollment rate and educational mobility in the sense of probability that children of high school graduates attend college. “Ave. HC” stands for the average human capital.

N. Other Policies Insuring against the Risks

This section studies two other policies that potentially insure against the risks associated with fertility choices under income uncertainty, other than the income-tested subsidy examined in Section 6: (1) wage insurance that provides cash benefits with households with a negative income shock and (2) fertility-dependent wage insurance that provides wage insurance benefits with households depending on the number of children they have.

Wage insurance provides workers facing negative income shocks (i.e., $z < 0$) with cash transfers. In the uniform wage insurance, I introduce the following payment function into the budget constraint for workers:

$$w_I(z) = \begin{cases} w_I & \text{if } z < 0 \\ 0 & \text{otherwise} \end{cases}$$

For the fertility-dependent wage insurance, I introduce the following payment function into the budget constraint for workers:

$$\tilde{w}_I(z, n, j) = \begin{cases} n \cdot \tilde{w}_I & \text{if } z < 0 \& j < J_{IVT} \\ 0 & \text{otherwise} \end{cases}$$

Under the fertility-dependent wage insurance, workers facing a negative income shock receive wage insurance benefits proportional to the number of children younger than 18 that they have.

I implement the introduction of these policies in an expenditure neutral way. More specifically, I feed the income-tested education subsidy into the model as I do in Section 6, and then set policy parameters for each cash transfer so that the short-run government expenditures of each policy is the same as those of the income-tested education subsidy. Also, I simulate each policy in a partial equilibrium setup to focus on the direct effects on fertility, controlling for indirect effects such as a GE effect and distributional effect.

The results are summarised in Table 20. Introducing fertility-dependent wage insurance increases fertility by 0.9%, whereas introducing uniform wage insurance has no effect on fertility. The insurance effects of the income-tested college subsidy on fertility, which result in a 1.3% increase in fertility, are more significant than those of these policies. This is because the income-tested college subsidy provides partial insurance not only against income risk but also against another source of uncertainty: uncertainty regarding children’s characteristics (i.e., psychic costs and innate abilities) and the associated uncertainty regarding the willingness to pay for children’s education.

	Fertility ($\Delta\%$)
Income-test college subsidy	+2.1%
Wage insurance (uniform)	+0.0%
Wage insurance (fertility)	+0.9%
